Modern ORs are equipped with ceiling-mounted boom arms for housing various surgical and anesthesiologic equipment (Figure 122.2). The boom arms provide ergonomic advantage in moving various equipments perioperatively. Video monitors can be placed as per the surgeon's/assistant's individual requirement to minimize neck strain. Additionally, the use of boom arms means there will be fewer cables and trolleys occupying the floor space, making movement better and faster, and assisting with cleaning. Studies have shown small but significant advantage of boom arms over conventional cart system in terms of anesthesia preparation time and surgical procedure preparation/turnover time, especially in laparoscopic surgery [1–3]. Three boom arms are generally required to house all suspendable items. However, boom arm systems do have disadvantages: they are significantly more expensive than floor carts; the minimum height and width requirements of the OR are more stringent; equipment that needs to be moved in and out of the OR cannot be placed on the boom arms; and there may be the hazard of equipment collision and arm malfunction/disconnection. Nevertheless, with advancing technology, the boom arm system seems here to stay.

The recommended size of a fully functional endourologic OR is 23×23 square feet floor and 12-feet high false ceiling; a 2-feet gap above the ceiling is used to accommodate cables, wires, pipings, and air conditioning vents [4]. The floor design of an endourologic OR is of paramount importance for hygienic and efficient

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

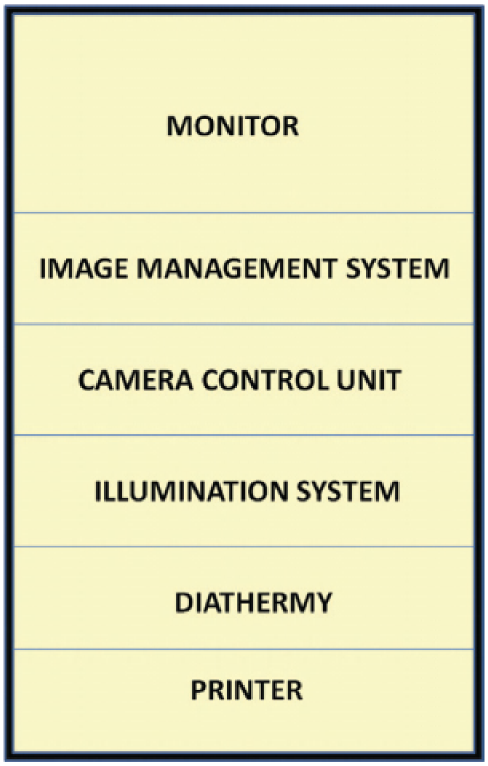

Figure 122.1 Set-up of an endoscopic video cart for lower tract endoscopy.

drainage of fluids that are part and parcel of endourology practice. It is recommended that there is a drain in the center of the OR with a slight slope of the floor towards it from all the walls [4]. In the absence of such a drainage system, a powerful active suction device should be available for suction of fluids directly from the patient drapes (Neptune Waste Management System, Stryker®, Kalamazoo, MI, USA).

There should be ample room for storage of instruments, equipment, and consumables both within the OR and in a central storage place close to the OR. Typically, a modern OR has storage shelves flush mounted in the OR walls and sealed with sterile jointing system.

Lighting

It is important to have an appropriate level of lighting throughout the OR and this will differ in different places. The sterile area must have at least 1500 Lux and rest of the room 500 Lux of light intensity. The recommendation for operating area lights is a shadowless white light as high as 3×10^5 Lux at 1-m distance for a twin-dome system. The modern operating area lights are predominantly of two types; halogen and more recently, LED (light emission diode); the latter provide high-quality cold white light and are more durable than

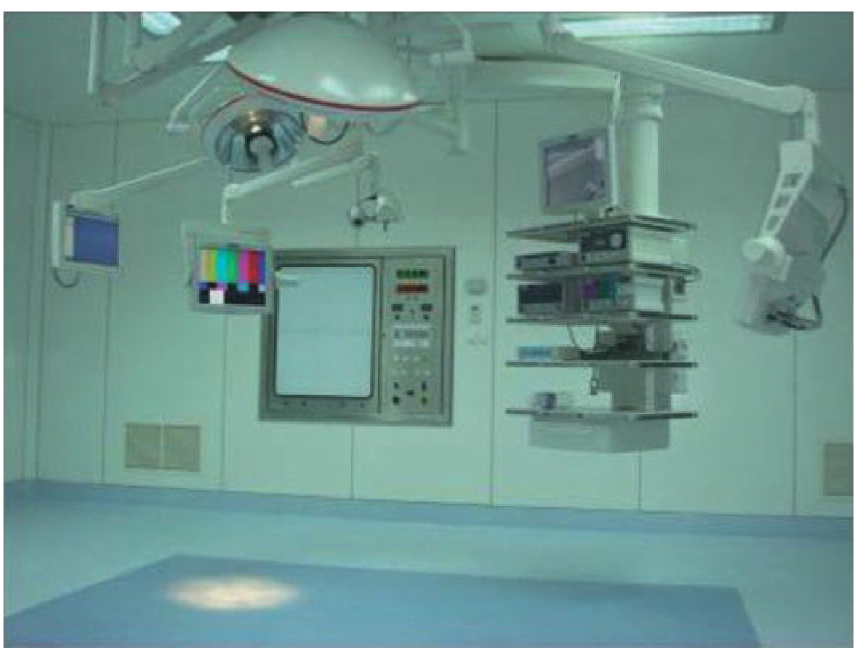

Figure 122.2 Operating room set-up on boom arms. Note the absence of cables, wires, tubings and carts on the floor.

the former. The operating area lights are mounted on boom arms and should have free vertical as well as horizontal mobility. Regulation of lighting level (graded dimming, on–off) is also important during a case. The various lighting controls should be available to the surgeon in the sterile field (touch screen monitor) as well as on a conveniently placed OR control panel. The latter can also regulate the clock, timer, temperature, and humidity.

Operating room table

The patient table must be made of rust-proof stainless steel. It should be easily movable on built-in wheels with central locking. To accommodate a large variety of surgical procedures, it should consist of separable head and leg sections, and have the facility for attachment of various stirrups for lithotomy position and attachment of a collection device (either ring or basin), and preferably a gynecological cut-out at the tail end of the body section. It should be capable of various positions (up/down, Trendelenburg/reverse Trendelenburg and lateral tilt). The controls for positioning the table should be available on a remote control (and also preferably on a touch screen monitor accessible to the surgeon). The table should be radiolucent and have an eccentrically placed base to accommodate a C-arm intensifier for intraoperative use of fluoroscopy.

Documentation

Archival of patient-related data for later referral and follow-up is important not only for clinical management, teaching and research, but is also a legal requirement for medicolegal purposes. Archival is performed in the physical form and/or electronically. Electronic record keeping has been available for decades and continuing advances in information technology have led to more widespread use of convenient and comprehensive archiving of text as well as graphic, image, and video data. The advantages of electronic archival are more complete archival, and more accurate and comprehensive recall. Moreover, much less space is required.

Hospital Information System is the most widely used electronic archival system and is used to manage hospital administrative, financial, and clinical records. It works using the Health level seven (HL7) protocol. In medical imaging, electronic picture archiving and communication systems (PACS) have been developed in an attempt to provide economic storage, rapid retrieval of images, access to images acquired with multiple modalities, and simultaneous access at multiple sites The universal format for PACS image storage and transfer is DICOM (Digital Imaging and Communications in Medicine). Nonimage data, such as scanned documents, may be incorporated using consumer industry standard formats like PDF (Portable Document Format), once encapsulated in DICOM. A PACS consists of four major components: imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI), a secured network for the transmission of patient information, workstations for interpreting and reviewing images, and archives for the storage and retrieval of images and reports.

In the modern OR, there should be an electronic workstation located in one corner. The workstation has inputs from various audiovisual devices in the OR (e.g. cameras – endovision, overhead, room camera; C-arm; ultrasound, etc.). It also has a computer connected to the HIS and PACS for ready referral to archived data and input of new data.

Another important aspect of a modern OR is the ability to relay audiovisual information (images, live video) to various places, e.g. the surgeon's office, lobby, and auditorium. Most surgical meetings devote a major session to the live operative workshop. Often, live transmissions are performed by erecting temporary facilities, which involves high cost without providing optimal quality. If the transmission facilities are frequently used either for conference workshops or teaching, then it makes sense to install these facilities during construction of the OR. Once the cabling is installed, there are no recurrent cost and, in the long run, this is economic (Figure 122.3).

Integration of the operating room

In the last few years it has become clear that the OR of the future needs to be integrated to optimize space, efficiency, and intraoperative decision-making. The surgeon's working environment has already undergone drastic changes, especially with the popularity of minimally invasive techniques in surgery. The development of these techniques and other technologies have made the OR suite progressively more complex and more difficult to manage.

A centralized OR with sterile controls minimizes this complexity by integrating minimally invasive surgical equipment, X-ray, ultrasound, video recorder, telephone, video printer, MRI, and other components, so that the nurse and surgeon can operate the components from a single interface.

Set-up for a surgical procedure

A number of procedures can be performed via the retrograde transurethral portal of entry, e.g. cystoscopy (CPE), transurethral resection of bladder (TURBT) or prostate (TURP), visual internal urethrotomy (DVIU), and various laser procedures on the prostate or bladder,

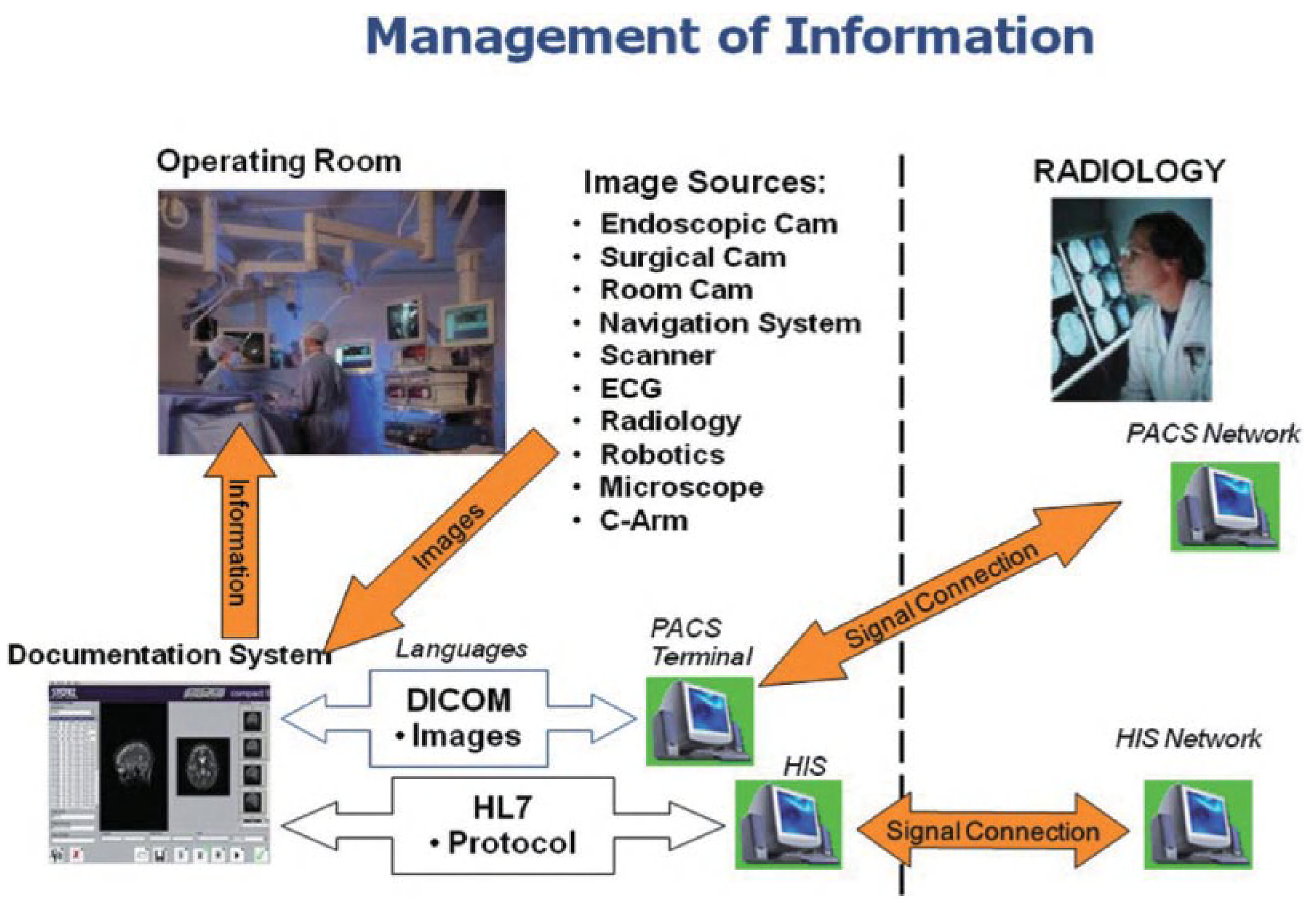

Figure 122.3 Data management in a modern operating room.

etc. For most procedures, two nurses are optimally required for set-up and smooth functioning during the case. Endourologic instrumentation and equipment will vary depending on the operative procedure.

With current advances in the understanding of the pathophysiology of urinary incontinence and pelvic organ prolapse, most of these can be managed through the vaginal route with/without use of graft material. Similarly, prostheses are increasingly being placed for urinary incontinence (artificial urinary sphincter) and for erectile dysfunction (inflatable or malleable penile prosthesis). The OR therefore should be equipped to tackle all these procedures.

The scrub nurse is responsible for setting up the instrument-table; to ensure that the instruments are adequately sterilized as per protocol; all instruments, telescopes, and accessories (electrosurgical unit, laser, light source, suction, etc.) are working properly; and everything on the table is neatly arranged and connected for easy availability. It is advisable to have some sort of a check-list so that "nothing" is missed. The scrub nurse is assisted in this process by the circulating nurse. While the scrub nurse is preparing the sterile set-up, the circulating nurse reviews the patient's chart. The circulating nurse acts as the patient's advocate, reviewing the OR sequence with the patient, identifying the correct operative site and laterality, addressing any concerns the patient may have, and communicating with the patient's family.

Antibiotics and prophylaxis against deep vein thrombosis (DVT) must be available if indicated. The availability of blood products for possible transfusion should be checked before the circulating nurse brings the patient into the OR.

After the anesthesia, the patient is usually placed in the lithotomy position. This is the most commonly employed position, although some procedures can be performed in the supine position (e.g. penile prosthesis). The patient's legs are raised slowly and simultaneously by two team members and positioned in gel-padded foot-rest stirrups (Figure 122.4), and the buttocks are extended over the table edge. Precautions must be taken to prevent pressure on the peroneal, saphenous, posterior tibial, popliteal, and sciatic nerves. Flexion, extension, and compression due to incorrect positioning of the legs can result in nerve damage, venous thrombosis,

Figure 122.4 Allen Yellofin™ lithotomy stirrup (Allen Medical System, Leicester, UK). Note the ergonomic positioning of the monitors (hung from the spring arm).

compartment syndrome, and hip-joint dislocation. For a lengthy procedure, antiembolic stockings and compression sleeves are used. Both arms should be secured on padded arm boards to prevent injury to the patient's fingers or hands when the table is raised or lowered.

Once the patient is positioned, a patient plate is fixed distant to bony prominences for use with monopolar diathermy. After removal of any visible contamination, the minimum necessary clipping of hair is performed with an electric clipper; this may even be omitted in certain circumstances. Shaving of hair is not recommended, nor is part preparation before coming to theater, since there is a proven association with increased risk of infection [5]. Next, skin preparation is done using antiseptic solutions; the iodophors (e.g. povidone–iodine), alcohol-containing products, and chlorhexidine gluconate are the most commonly used agents. A recent randomized controlled study concluded in favor of 2% chlorhexidine gluconate and 70% isopropyl alcohol compared to 10% povidone–iodine for preventing superficial and deep surgical-site infections in clean–contaminated surgery [6]; we typically use the former for the same (Chloraprep®; CareFusion, El Paso, TX, USA). With the apprehension of infection associated with prosthetics (e.g. artificial urinary sphincter, penile prosthesis), it is common practice to manually scrub the parts using povidone–iodine or chlorhexidine for 10 min after positioning the patient.

Transurethral surgery

After standard draping, attachments for collection of irrigant fluid/tissue must be ensured before starting the procedure. Various proprietary drapes are available with inbuilt collection systems (Kimberly-Clarke®, Reigate, Surrey, UK; Microtek Medical, Columbus, MS, USA; G Surgiwear, Shahjahanpur, UP, India). Commonly, the outlet of the collection device is attached to a large dual-suction device in order to prevent spillage.

A typical set-up for transurethral resection is described below.

Equipment

This consists of one back table for the set-up, one prep table, one single-ring stand, energy generator (monopolar, bipolar, laser), and vision tower.

Instrumentation

This consists of a camera system, telescopes, urethral sounds (Vanburen), a cystoscopy tray, and a resectoscope tray (separate for monopolar, bipolar, laser).

Set-up

This consists of an open prep tray on the prep table, a disposable cystoscopy pack on the back table, and a cystoscopy basin on a single-ring stand.

Figure 122.5 Resectoscopes: (A) monopolar (Karl Storz, Tuttlingen, Germany); (B) bipolar (Gyrus-ACMI, Southborough, MA, USA); and (C) Holmium laser (Richard Wolf, Knittlingen, Germany). All resectoscopes have similar components, i.e. outer sheath, inner sheath, deflecting tip obturator, working element.

Back table

The cystoscopy pack consists of a back table drape, patient drapes, irrigation "Y" tubing/TUR set, k-y jelly, a marker pen and labels for labeling fluids, a 10- and 20-mL syringe, a Telfa pad (Kendall, Covidien, Mansfield, MA, USA) for specimens, a disposable graduate, two small basins, and three disposable towels.

Prep table

The scrub nurse will set up the prep table with five sponges for prepping the patient and place another five sponges on the cystoscopy table for use on it. Patient drapes are placed in the left lower corner of the back table. All cords to be passed off are placed in the left upper corner of the back table (camera, light cord, cysto "Y" tubing, Bovie or bipolar cord). A towel with k-y jelly on it is placed beside the drapes. The Vanburen sounds are then placed in sequential order from smallest to largest. Next, the 22F cystoscope sheath and obturator, 0° telescope, 30° telescope with double channel bridge attached, and 70° telescope with single channel bridge attached are placed. Next to these the resectoscope set is placed, which consists of (Figure 122.5):

• *Monopolar resection*: continuous flow resectoscope set 26F/28F: outer sheath, inner sheath, visual obturator with single channel, Timberlake deflecting tip obturator, passive type/active type (surgeon's preference) working element for the resectoscope, and disposable loop (of the surgeon's choice for resection). A Toomey syringe/Ellik's evacuator is also placed to use at the end of the case for irrigating the bladder and evacuating any specimen from the bladder. 1.5% Glycine is the irrigating fluid of choice for monopolar resection, and 0.9% normal saline for continuous irrigation postoperatively. Adequate amounts of both must be available for an uninterrupted procedure.

• *Bipolar resection*: Gyrus PK® Superpulse® (Gyrus ACMI, Southborough, MA, USA) has been the most extensively studied and is the most widely used generator. (The set specific to this manufacturer includes a

25.6F/27.6F inner and outer sheath, visual sheath, Timberlake obturator, Iglesias working element, and disposable loop. 0.9% Normal saline is the irrigant of choice for this procedure. Bipolar set-up confers certain advantages: lower incidence of dilutional hyponatremia by virtue of using normal saline rather than glycine for irrigation, and less scatter of current (decreased incidence of obturator jerk and safe in patients with a pacemaker).

- *Laser resection*: holmium:YAG and KTP are commonly used lasers for prostate diseases. The resectoscopes/cystoscopes for these are different from the above as well as from each other. The basic set has similar components (i.e. outer sheath, inner sheath, obturator, working element), but their working elements have specially designed working channels to accommodate the laser fiber.

Penile prosthesis

Equipment

This consists of one prep table, one back table, two Mayo trays, two double-ring stands, and an electrosurgical unit.

Instrumentation

This consists of a urology minor tray, penile prosthesis tray, and a cantilevered retractor.

Supplies

These include one 10-mL syringe, three 20-mL syringes, two 60-mL syringes, one 14F Foley catheter and urine drainage bag, one Steri-Drape, a Lone Star retractor with hooks, a dilamezinsert inserter, a #15 surgical knife blade, a needle protector, a marker pen and labels for medication, a pencil for monopolar diathermy, bipolar diathermy forceps, and suction tubing. It is of paramount importance to ensure all components of the prosthesis are available in various sizes in the OR before the patient is brought into the OR.

Set-up

This consists of an open prep tray on the prep table, an open major pack (table cover, five half sheets, two wet-proof drapes, 12 towels, one Mayo tray cover, two wet-proof towels, and four gowns) on the back table, an open major basin set on each ring stand, one extra half-sheet, and one extra Mayo tray cover.

Circulating nurse

The circulating nurse must ensure the patient has received appropriate antibiotics when they come into the OR, and have appropriate antibiotics ready to place on the sterile field for irrigation when the scrub nurse is ready. They must record all items used on the room record and fill out all appropriate implant documentation. For DVT prophylaxis we always place sequential compression devices on the patient prior to induction of anesthesia.

Scrub nurse

The table is set up in the usual way. Instruments from penile prosthesis tray are placed in an extra rectangular basis and soaked in antibiotic solution (Hegar dilators, nasal speculum, measuring device, dilamezinsert, furlow tool, and quick connect device). Both Mayo trays are draped in the usual fashion; in addition, one of these is also draped with an impervious Steri-Drape. A small round basin, a large round basin, and a rectangular basin, along with all the syringes are placed on this Mayo tray (this is the prosthesis Mayo and anything placed on it should be rinsed in sterile water beforehand). The small basin is used to keep rubber-shod mosquito clamps, the large basin for plain 0.9% normal saline to fill the device with, and the rectangular basin to place the device for preparation. The 10-mL syringe is used for the Foley catheter, the 20-mL syringes for flushing the prosthesis tubings, and the 60-mL syringes to fill the device and reservoir. The four major basins should be filled with sterile water and two are placed on each side of the patient for the resident and surgeon to use to wash and rinse the blood from their gloves prior to handling the prosthetic device. Normal saline on the field will have antibiotics placed in it for irrigation (except as stated on the prosthesis Mayo). On the other Mayo (nurse's Mayo) there should be Adson forceps, short DeBakey forceps, suture scissors, metzenbaum scissors, four straight hemostats, four curved hemostats (all of which are used to tag closing stitches placed in the corpora prior to placing the prosthesis), one Allis clamp, and one Lahey dissector.

Device preparation

Preparation will depend on the type of device and the manufacture's guidelines.

Artificial urinary sphincter prosthesis

The set-up is more or less similar that for a penile prosthesis. The supplies should include a ¼-inch Penrose drain (to place around the urethra), kittners (to assist with dissecting around the urethra), and methylene blue if needed to test for urethral integrity. Hegar dilators, nasal speculum, measuring device, dilamezinsert, furlow tool, and quick connect device are not required.

Vaginal surgery (e.g. mid-urethral sling, cystocele repair)

The OR set-up described above is sufficient for vaginal surgery as well. Specifically, the table must have a gyne-cut to allow space for the vaginal speculum/retractor, and the lithotomy poles must be capable of full/extended lithotomy. In addition, certain special instruments, e.g. weighted vaginal retractor, Lone Star retractor, Breisky–Navratil vaginal retractor, Sim's speculum, Stamey needles, Heaney curve-tipped needle holders, and Mueller S-shaped dissecting scissors, etc., may be useful (Figure 122.6).

Equipment

This consists of one prep table, one back table for set-up, two Mayo trays, one double ring stand, one Bovie, and one video tower.

Instrumentation

This consists of a urology minor tray, sling specials, and a cantilevered retractor, and towards the end of the case, a cystoscopy set (instruments, telescopes and camera). Instruments used include toothed forceps, short DeBakey forceps, suture scissors, Metzenbaum scissors,

Figure 122.6 Vaginal surgery instruments. (A) (left to right) Breisky–Navratil vaginal retractors, Deaver retractors, Sim's speculum; (B) (top to bottom) S-shaped scissors, bubble tip scissors, Heaney curved needle holder; (C) weighted vaginal retractors; (D) Lone Star retractor.

Strulley's and Church scissors, two curved hemostats, one Lahey dissector, and one long Allis clamps and one Kelly clamp with a kittner. The surgeon will start out using a weighted vaginal retractor.

Supplies

These include a Lingeman-type GYN-Surgery Drape Pack, two 10-mL syringes, two suction tubings (one for regular suction and one for the drain bag on the drape), a 16F Foley catheter, drainage bag, marker pen and labels for medication, Steri-Drape to isolate the rectum, kittners to assist with dissecting, surgical stay hooks, vaginal packing, surgical knife blade (#15), needle protector, injection needle (21G × 1 inch) and TUR tubing set.

Set-up

This consists of an open prep tray on the prep table, an open major pack (table cover, five half sheets, two wet-proof drapes, 12 towels, one Mayo tray cover, two wet-proof towels, and four gowns) on the back table, and an open major basin set on a ring stand.

Circulating nurse

If some type of sling/mesh is to be used, the circulating nurse must ensure the implant is available *before* the patient comes into the OR. They should arrange for DVT prophylaxis (sequential compression device), and have appropriate antibiotics and lignocaine 2% (local infiltration) ready to place on the sterile field for irrigation when the scrub nurse is ready. All items used should be recorded in the room record, and all appropriate implant documentation filled out.

Scrub nurse

The scrub nurse sets up the back table in the usual manner. They may have to pass the instruments over the patient's leg and also may have to hold the Allis clamp for traction; therefore, the scrub nurse should ensure availability of several step-stools because the patients are generally in the lithotomy position with Yellofin stirrups, and some in the Trendelenburg.

Pharmacy

The following are required: antibiotic-impregnated vaginal packing (e.g. bacitracin, clindamycin, povidone–iodine), saline and water (3-L bag of saline for cystoscopy), antibiotics for irrigation (bacitracin 50 000 U in 1-L of saline), and bupivicaine 0.5% or 0.25% (with or without 1:200 000 epinephrine) to inject into the vaginal mucosa at the beginning of the case to help with dissection of the mucosa.

Universal protocol

The Joint Commission (JC) on Accreditation of Healthcare Organizations approved a Universal Protocol (UP) for preventing wrong site, wrong procedure, and wrong person surgery in July 2003, and it became effective on July 1, 2004 for all accredited hospitals, ambulatory care, and office-based surgery facilities [7]. The UP consists of three distinct sections: preprocedure verification, site marking, and a time out performed immediately prior to the procedure. The UP is applicable to any setting where invasive procedures are performed, not just the OR setting.

In accordance with the above regulation, before starting any intervention on the patient, all personnel in the OR use a "time out" to identify (1) correct patient, procedure, site, side, position, equipment, implants, images, medicines (labeled); (2) allergies and antibiotics; and (3) whether all labels from the previous case have been removed from the OR.

The World Health Organization (WHO) has realized the importance of the UP, and following its success in the USA, in 2005 it designated the JC and JC International (JCI) as the WHO Collaborating Center for Patient Study Solutions. Medical institutes must adhere to the UP to be considered as following "patient safety goals" and before acquiring JCI accreditation; 39 countries have already enrolled in the program.

Hazards

Laser

Laser technology has seen a booming market in urology. Innumerable lasers have been explored for various indications, e.g. resection/ablation of prostatic tissue, fragmentation of urinary tract stones, and ablation/incision of urinary tract stricture. The two most common lasers used in the USA are the holmium::YAG and Green Light™ lasers.

The laser produces an intense, highly directional beam of light. If directed, reflected, or focused upon an object, laser light will be partially absorbed, raising the temperature of the surface and/or the interior of the object, and potentially causing an alteration or deformation of the material. With increasing use of lasers in urology, it becomes imperative to be fully aware of their potential hazards and the safety standards necessary to prevent/treat these. There is scope in this chapter to describe important aspects only of laser safety and hazards. The reader can refer to http://www.laserinstitute.org/ for a comprehensive understanding of lasers.

Laser light can potentially damage eyes and skin. The effect varies with the frequency and intensity of the laser light. For example, KTP laser light, which is in the visible wavelength range (532 nm) causes retinal burns; whereas, holmium laser light, in the infrared range, damages more anterior parts of the eye, causing aqueous flare, cataract, and corneal damage. Although, skin is more protected from damage by laser, owing to the layer of dead cells and different absorption properties, healthcare lasers can cause burns, photosensitivity, and darkening. Laser also poses other hazards like electrocution, fire, and asphyxiation.

Therefore, all personnel in the OR must be aware of laser safety and comply with the mandatory safety regulations, both for their own safety and that of others. Undoubtedly, the most important part of the personal protective equipment (PPE) with regards to laser is the protective eyewear. It must be realized that the eyewear is wavelength specific; therefore, glasses that are protective for the Green Light laser are not suitable for the holmium laser, and *vice versa*. All personnel must wear appropriate eye-wear at all times until laser is no longer in use. The patient's eyes and eyelids should be protected from the laser beam in a method deemed appropriate by the laser safety officer. Any change in the status of the laser is must always be announced (e.g. active or standby). It must be remembered that there is no first-aid for laser exposure to the eye; therefore, prevention is the key. Appropriate warning signs, which preferably should include alarm lights, must be switched on outside all doors to the OR prior to the procedure. Any unwanted exposure to laser must be notified to the local authorities.

Realizing the high hazard potential of laser equipment, various governing bodies have drawn up mandatory regulations on safety standards for laser equipment as well as on safe practice by the user. In the USA, the Occupational Safety and Health Administration (OSHA) works to ensure safe working conditions for by setting and enforcing standards and by providing training, outreach, education, and assistance. It also governs laser administration. Complete documentation on laser use in healthcare is available in ANSI Z136.3-1996/2005 of the American National Standards Institute and all laser manufacturers must comply with these standards. The European equivalent standards are EN207/208/60825.

Radiation

Interventional fluoroscopy is an essential part of endourology; with advances in this field leading to more and more complex endourologic procedures, the exposure of the surgeon, staff and patients to fluoroscopy is increasing in parallel. The hazards of radiation to the patient include immediate or delayed skin injury and a small but real delayed risk of cancer. Studies from percutaneous transluminal coronary angioplasty have estimated long-term cancer risk to be 0.1% in men aged 60 years or older with exposure of 80 Gy/cm^2 (effective dose 20 mSv) [8]; the risk is estimated to be up to fourfold in children younger than 10 years [9]. The exposure of the surgeon during endourologic procedures is significantly less, yet still significant [10]. It is therefore important to be aware of the hazards of fluoroscopy and means of protection.

The recommendation for containment of radiation within the OR is a 2-mm equivalent of lead thickness in walls (a 15-cm thick concrete wall or a 25-cm brick/cement wall have equivalent radio-opacity) [6]. Adequate PPE, i.e. articulated shielding, lead aprons, gloves, thyroid shields, and glasses, must be available and must always be used. The minimum recommendation for lead garments is 0.25-mm lead thickness (optimum 0.35 mm) for protection against scattered radiation, and 0.50-mm lead thickness for protection against useful radiation. Two-piece lead aprons are ergonomically superior to single-piece ones in terms of back strain. There should be a visual indicator outside the OR whenever fluoroscopy is in use. All staff must be provided with dosimeters for periodic monitoring of radiation dose. The principles of proper shielding, minimizing time and radiation, and maintaining proper distance from the source are acronymed as ALARA (as low as reasonably achievable). The National Cancer Society has published guidelines for minimizing unnecessary radiation to patient and staff [11]. Documents on various concepts and recommendations on safe use of fluoroscopy are readily available from the International Atomic Energy Agency website [12].

Patient handouts

Patients undergoing any surgical procedure require both medical and nursing expertise. Preoperative teaching begins at the time of diagnosis. A short lesson that makes use of diagrams or models will help patients understand the anatomy of the organ system to be operated upon and assist in educated mutual decision-making. At the time of the initial consultation, the appropriate procedure is explained to the patient and any questions and concerns are addressed. Most often patients want to know the length of the procedure and hospitalization, the amount of pain and its treatment, and how long the recuperation period will be.

Prior to admission, a preoperative work-up is performed that includes a complete blood count, electrolyte measurements, urinalysis, and urine culture. If the urine culture is positive, the patient is treated preoperatively with antibiotics. Prothrombin time and partial thromboplastin time are determined if there is any history of

bruising or bleeding. An electrocardiogram (ECG) and chest X-ray are performed depending on the patient's age and medical history. On admission to hospital, the patient's radiographs are reviewed again and informed consent is obtained.

As much as for the treating surgeon, it is important for the patient to understand their medical condition, available treatment options (with pros and cons), and, after decision on surgical option, the benefits/risks of the procedure, surgical details, approach, instructions in the perioperative period, and restrictions/precautions until complete healing or in the long term. Needless to say, to assimilate such a plethora of information, more than one session with the clinical team is required. In a busy practice, even the treatment counselor may find it difficult to discuss each and every aspect of treatment in details. Moreover, the patient is unlikely to remember everything even after thorough counseling.

To overcome the shortcomings of verbal counseling, handouts are patient-friendly tools that provide instructions and information in black-and-white, and are always available for ready referral. These also help the patient to generate questions for a more effective counseling session. Often the handouts also include useful information like location maps, addresses, and contact numbers. Patient handouts should be written in simple and common language. The components that should be included are given in Table 122.1 and an example handout for an artificial urinary sphincter in Table 122.2.

Acknowledgements

We acknowledge Mr Anurup Majumdar, Karl Storz® India, New Delhi, India for his help with the sections on OR set-up.

Table 122.1 Items in a patient handout.

1. Introduction to the normal anatomy and function (brief with figure)
2. Description of the disease (preferably with figure)
3. Description of the proposed procedure (e.g. benefits, side effects, anesthesia, incision – location and length, duration, requirement of prosthetics, grafts, blood products, dressings and tubings; preferably with figure)
4. Preoperative preparation for the procedure:
– Any dietary change (e.g. clear liquids, with examples)
– Any bowel preparation (e.g. enema, golytely, laxative tablets, with description)
– Any part preparation (e.g. vaginal douching, pessary, hair clipping/epilation, bathing with antimicrobial soap)
– Any medication ingestion (e.g. antibiotics, sedatives, antacids, with clear mention of dosage and schedule)
5. Location of surgery center (with map) – time to report, helpline number, location of attached vehicle parking
6. Postoperative instructions:
– Attention to degree of discomfort (mention of pain, discharge, dressings and tubings, along with expected time of recovery)
– Instructions of care of wound (e.g. change of dressings, removal of catheter/other tubings, personal hygiene); description of each procedure clearly and separately
– Avoidance of certain activities along with duration of avoidance (e.g. straining, sexual activity); preferably mention the benefits
– When, where and whom to follow-up with (along with address with map of location)
7. Information on emergency symptoms and signs:
– Description of common/serious symptoms and signs (e.g. fever, pain in wound, discharge from wound, wound dehiscence, blockage of tubings)
– Emergency contact numbers, emergency location (along with map)

Table 122.2 Patient handout for an artificial urinary sphincter.

Description

Anesthesia

You will have general/spinal anesthesia before the procedure. The aim of anesthesia is to keep you free of pain during the procedure. You will be unconscious during the general anesthesia and numb (from waist down) during the spinal anesthesia. You may feel somewhat uncomfortable during induction of anesthesia.

Prosthetic device

This device is planned for your leakage/continuous dribbling of urine during activities which increase your belly pressure (e.g. walking, coughing, sneezing, laughing, lifting, or exercising). For your degree of leakage, alternative modalities, i.e. sling and injections in the urethra, may not work as well. You should discuss with your doctor in detail.

An artificial sphincter has three parts:

- Cuff: fits around your urinary passage (named "bulbar urethra");
- Balloon/bulb: placed under your lower belly muscles to one side;
- Pump: placed in the scrotum (for men).

The cuff is always in the inflated state to keep your urethra in the closed state (to prevent urinary leakage). At the time of voiding, you will press the pump a few times to empty the cuff water back into the balloon; it will fill up again automatically in ~1½ min.

You will have two small cuts, one each in the following locations to fit the device into place:

- Lower belly: for balloon and pump;
- Perineum: for cuff.

Please note, the device will *not* be active for 4–6 weeks immediately after the procedure for optimum healing. This means you *will* remain incontinent during this period and will have to use pads as you are using now.

Adverse effects and risks

This procedure is generally safe; however, any intervention may be associated with some risks and adverse effects (e.g. infection in the cut, opening up of the cut, clotting of blood in the legs, breathing problems/pneumonia, bleeding, etc.).

Risks for this surgery:

- Injury to the urethra or other adjacent organs (which may need an additional procedure and/or postponement of insertion of the device);
- It may become difficult to empty your bladder after the procedure (which may need catheterization);
- Urine leakage may not disappear completely;
- Malfunction/infection in the device (which may necessitate removal of the device).

Instructions prior to the procedure

Always tell your caretaker doctor/nurse what medications (prescription/over the counter) you are taking. Always tell them what other medical conditions or allergies you are suffering from. Any such information may be important for the clinician, e.g. medicines like blood thinners (Aspirin, clopidogrel, warfarin) need to be stopped a few days before the procedure; some medicines are permissible/desirable to continue through the procedure.

Your doctor will test your urine to make sure you do not have a urinary infection before starting your surgery.

On the day of your surgery:

- You will usually be asked not to drink or eat anything for 6–12 h before the surgery;
- Take the medicines your doctor told you to take with a small sip of water;
- Your doctor or nurse will tell you when to arrive at the hospital.

After the procedure

You may return from surgery with a tube in place in your urethra for draining urine from your bladder for a little while. It most likely will be removed before you leave the hospital. Your expected stay in the hospital will be less than 24 h. Please note that the final decision of length of stay will be decided by the clinicians in your best interest; they may want to watch you for a longer period – for your benefit.

About 6 weeks after surgery, you will be taught how to use your device; until then you will remain incontinent. You will need to carry a wallet card or wear medical identification that tells healthcare providers you have an artificial sphincter. The artificial sphincter must be turned off if you need to have a urinary catheter placed.

Outlook (prognosis)

Most people have significant benefit in terms of incontinence and improvement in quality of life after this procedure. You may become completely dry of urine and at least much less wet than before. Very few people may not benefit from the procedure at all. Generally, the benefit of the device remains for some 8–10 years and tends to wear away with time. This happens because of slow thinning (atrophy) of the urethra where it is inserted due to constant pressure; in such event, a new cuff needs to be surgically placed in a healthier part of the urethra.

CHAPTER 123

Local Anesthesia for Minimally Invasive Treatment of the Prostate in the Office Setting

Jay Hollander & Damon Dyche
William Beaumont Hospital, Department of Urology, Royal Oak, MI, USA

Introduction

Despite a wealth of information regarding outcomes for most minimally invasive treatment (MIT) options for lower urinary tract symptoms caused by benign prostatic hyperplasia (BPH), there are a dearth of studies regarding the best method of local anesthesia for prostate procedures. No "standard" exists with respect to the office-based anesthetic protocol.

During the past decade, as minimally invasive techniques have proliferated, reimbursements for hospital-based procedures have diminished, while reimbursements for office-based procedures have increased. Physicians in private practice have increasingly sought to perform procedures in the office. Microwave procedures could be performed without intravenous analgesia [1]. Urologists also found transurethral needle ablation using radiofrequency energy and interstitial laser coagulation could be performed with local anesthesia in the office [2–4]. Currently, urologists are performing and developing techniques for safe and comfortable laser ablation of the prostate in the office setting. Such a trend may change as reimbursement changes; nevertheless, an in-office procedure has a potential to be safer (in that only local anesthesia is used), more convenient and efficient for the patient. Such procedures are also less costly overall, saving on hospital/surgery center fees and professional anesthesia charges. Whether urologists continue to develop and advance in-office MIT remains to be seen. Urologic outcomes should be similar to procedures performed in the hospital or surgery center with full anesthesia or intravenous sedation. True evidence-based conclusions comparing procedures performed with anesthesia and anesthetic monitoring to those performed under local anesthesia in the office do not exist.

This chapter will discuss the common pharmacologic agents that can be used as local anesthetics, and the application and techniques used to deliver local anesthesia. The techniques used to anesthetize the prostate for MIT are in evolution. It is hoped that the information presented will stimulate proper study for the development of improved local anesthetic protocols and techniques. Any local anesthetic protocol for the performance of MIT of the prostate in the office setting should have the following goals: (1) to provide satisfactory anesthesia such that the patient and surgeon feel comfortable with the performance of the procedure in the office setting; (2) to safely administer the anesthetic so that proper patient monitoring requires nothing more than vital signs and observation; (3) to minimize the risk of complications or bleeding that might interfere with proper performance of the procedure; (4) to carry out the MIT in a fashion that is complete and not compromised by the fact that local anesthesia is used instead of regional (i.e. spinal) or general anesthesia.

Patient selection and preparation

In order to enhance the likelihood of patient acceptance and comfort, preoperative counseling is paramount. The experienced urologist should also develop the skill of

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

patient selection, much like that in selecting patients for in-office vasectomy and cystoscopy. Patient size, prostate size, and patient comfort level with the office physical examination and preoperative counseling need to be taken into account. Patients should be counseled on the likelihood that they will not be fully anesthetized such that they will not be numb to all feeling. Some discomfort should be expected but this should be mild and generally well tolerated. Time should be spent explaining the delivery technique of the local anesthetic so that patients know what to expect.

Pelvic neuroanatomy

The following is a brief discussion of the relevant prostatic and urethral neuroanatomy. With a basic knowledge of genitourinary innervation, it is easier to understand which nerves can be appropriately targeted for prostatic and posterior urethral anesthesia.

The inferior hypogastric (pelvic) plexus receives both sympathetic (hypogastric nerve) and parasympathetic (pelvic splanchnic nerve) innervation. The plexus is a 4–5-cm long rectangle and its midpoint reaches to the tip of the seminal vesicles [5]. It runs on either side of the rectum, communicating behind the rectum and sending branches to encompass the vesical neck (Figure 123.1). The distal end of the pelvic plexus gives off branches to the posterior lateral aspect of the prostate, running in close association to the arterial and venous supply (neurovascular bundle) [6]. The nerves lie in the lateral endopelvic fascia near its junction with Denonvilliers' fascia [7]. The nerves then coalesce at the apex of the prostate at the 5 and 7 o'clock positions [8, 9]. Superficial branches innervate the urethral sphincter at the 3 and 9 o'clock positions, while deep branches are sent to the bulbourethral glands. As the cavernous nerves reach the penis, branches innervate the urethra at the 1 and 11 o'clock positions, while small branching fibers join the dorsal nerves of the penis [4, 5].

The pudendal nerve originates from Onuf's nucleus in the sacral spinal cord (S2–S4), leaves the pelvis between the piriformis and coccygeus muscles, and enters the greater sciatic foramen [10]. It then re-enters the pelvis through the lesser sciatic foramen and passes through the pudendal canal. Branches are sent off to the rectum (inferior rectal nerves), perineum (perineal nerve), and penis (dorsal nerve of the penis) [11]. The urethral sphincter has both autonomic and somatic innervations. Hollabaugh *et al*. performed a study of 12 fresh cadaveric dissections and confirmed the presence of an autonomic (pelvic nerve) and dual somatic (intrapelvic pudendal and perineal nerve) innervations of the rhabdosphincter [12].

From these descriptions it can be reasoned that a local anesthetic delivered anywhere from the seminal vesicles

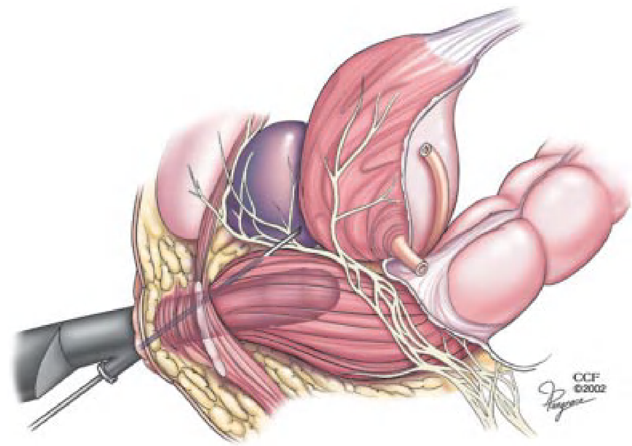

Figure 123.1 Prostatic neuroanatomy. The inferior hypogastric (pelvic) plexus lies on either side of the rectum and its midpoint stretches to the tip of the seminal vesicles (reproduced with permission from Dr Stephen Jones and the Cleveland Clinic Foundation).

to the apex of the prostate should have some effect on sensory input from the prostate. Likewise, the rhabdosphincter could also be affected by nearby local anesthetics.

Local anesthetic pharmacology

Local anesthetics act by inhibiting voltage-gated sodium channels that allow sodium ion influx into the nerve. This results in membrane stabilization and inhibition of neuronal action potential [13]. Amide local anesthetics are the most common class of anesthetics used by urologists. Allergic reactions are class specific, meaning that a person may have a hypersensitivity to multiple anesthetics in the same class [13].

The addition of epinephrine (1:200 000) can provide vasoconstriction. This will decrease blood flow to the injected area, decrease intraoperative bleeding [14], and causes a slower reabsorption/extended effect. Epinephrine should not be injected into areas that are supplied by end-arteries (fingers/toes, glans penis, nose, etc.).

Amides are common local anesthetics used in urology and include lidocaine, bupivacaine and mepivacaine (Table 123.1). Lidocaine is the most commonly used local anesthetic and it is well known to urologists. It can be given as a 0.5% or 1% solution at a maximum dose of 3–5 mg/kg. The onset of action is 2–5 min and it has duration of action of 30 min to 2 h [15]. A 0.5% solution provides 5 mg/mL, so an 80-kg person can receive up to 80 mL of a 0.5% lidocaine solution or 40 mL of a 1.0% solution.

Bupivacaine has more than twice the duration of action of lidocaine. A full dose of bupivacaine is

Table 123.1 Common local anesthetics used in urology (from Berde and Strichartz [13], with permission).

	Concentration (%)	Dose (mg/kg)	Onset (min)	Duration (h)
Lidocaine	0.5–1.0	3–5	2–5	0.5–1
Mepivacaine	0.5–1.0	4	3–5	1–1.5
Bupivacaine	0.25–0.5	1–2	2–10	2–4

Table 123.2 Oral medications for minimally invasive prostate therapy [15, 47].

	Dose (mg)	Onset (min)	Duration (h)	Toxicities
Benzodiazepines				
Diazepam	5–10	45–90	2–4	Respiratory, seizures, anaphylaxis
Lorazepam	1–2	45–90	6–12	Respiratory, seizures, anaphylaxis
Alprazolam	0.25–0.5	60	6	Respiratory, seizures, anaphylaxis
NSAIDs				
Naproxen	220	30–60	7–12	Gastrointestinal, bleeding, renal
Ketorolac	10	30–60	4–6	Gastrointestinal, bleeding, renal
Narcotics				
Hydrocodone/acetaminophen	1–2 tabs (5/500)	10–30	4–6	Respiratory, constipation
Oxycodone/acetaminophen	1–2 tabs (5/325)	10–30	4–6	Respiratory, constipation
Anticholinergics				
Hyoscyamine	0.125	2–3	4	Gastrointestinal, urinary retention, dry mouth

1–2 mg/kg, or 3 mg/kg in combination with epinephrine. A 0.25% solution provides 2.5 mg/mL of bupivacaine, so an 80-kg person can receive up to 64 mL of a 0.25% solution or up to 32 mL of a 0.5% solution. There is a known toxicity of ventricular arrhythmias/cardiac arrest with overdosing [15].

Mepivacaine is dosed at up to 4 mg/kg with a quick onset of action of 3–5 min and a duration of action of 45 min to 1.5 h. A 0.5% solution provides 5 mg/mL of mepivacaine, so an 80-kg person can receive up to 64 mL of a 0.5% solution or up to 32 mL of a 1.0% solution. Toxicities include central nervous system (CNS) side effects/seizures and bradycardia/heart block [15].

In general, toxicities can occur if an overdose of anesthetic is given, or if the anesthetic is mistakenly injected into the vasculature. Proper infiltrative techniques, including a fundamental knowledge of the surrounding anatomy and aspiration prior to injection of the anesthetic, help to avoid these complications. CNS side effects include a spectrum of symptoms from tinnitus and metallic taste in the mouth to seizure activity. Cardiovascular side effects range from bradycardia, atrioventicular block, and ventricular arrhythmias to cardiac arrest [15]. Allergic reactions can occur at any dose if there is a hypersensitivity, and can cause anything from hives to overt anaphylactic shock. Amide anesthetics are metabolized by the liver and excreted by the kidneys, so the dosage should be decreased in patients with either liver or kidney failure [13]. For the purpose of local anesthetic for MIT of the prostate, the doses needed for a reasonable block seem to be well below anything close to the maximum dose, making toxicities very unusual. Lidocaine is clearly the most commonly used agent in the office setting.

Oral supplementation

Virtually all office-based MIT protocols for the prostate involve preoperative oral medications to mitigate pain, anxiety, and bladder symptoms. As such, oral pain medicines, sedatives, and antianxiety medications are often considered along with anticholinergics. These preoperative "cocktails" are developed by word of mouth, with urologists sharing experiences as they bring a MIT into the office. The use of oral medications, while likely very beneficial to patients, has not been studied in a way that allows "best practices" to be established. It can be safely said that the preoperative medications used are generally very well understood by urologists, who use similar medicines in the day-to-day management of their patients (Table 123.2). Any study of local anesthesia for MIT of the prostate will be hampered by the added effects of these oral medications. If a local anesthetic technique is capable of working alone for a specific MIT, it must be

proven as effective without oral supplemental agents. Nevertheless, preoperative oral medications that add to patient comfort and safety are clearly appropriate.

Topical urethral anesthesia

Prior to flexible cystoscopy being available, urologists routinely performed rigid diagnostic cystoscopy in the office with or without an anesthetic gel, such as 2% lidocaine. There is no question that a significant number of patients found the exam very uncomfortable and rarely would any patient suggest there was no discomfort at all. Urologists experienced with rigid cystoscopy understood that most of the discomfort tended to occur as the scope traversed the membranous and prostatic urethra, straightening the bulbous and proximal urethral anatomy. Patients reflexively resist cystoscopy by tightening the perineal musculature and membranous urethra. However, once in the bladder, patients would often relax with the words "the worst part is over". The diagnostic cystoscopy could then be completed in most instances. Again, patient selection was still very important in enhancing the odds of a successful procedure.

Though lidocaine gel has been used for decades for cystoscopy in males, the proof that it works well as a local anesthetic is lacking. Stein *et al.* showed no benefit of lidocaine gel compared to a water-based lubricant for rigid cystoscopy in males in a prospective randomized controlled double-blind study [16]. Dwell time for the lidocaine was 5–10 min. In an effort to see if dwell time was insufficient, Goldfischer *et al.* performed a similar study using 30 mL of 2% lidocaine gel with a dwell time of 20 min before cystoscopy, comparing this to water-soluble lubricant. They found a slightly significant difference in patient perceived pain scores [17]. Both lidocaine gel and lubricant-only groups had discomfort and perhaps the difference was not clinically significant, as urologists could not differentiate who received lidocaine and who did not. There are numerous modern studies suggesting that 2% lidocaine works no better than water-soluble lubricant for flexible cystoscopy in the male [18–22].

It is therefore of interest that virtually every publication of in-office MIT of the prostate discusses some form of topical lidocaine instillation transurethrally. It is likely that very little lidocaine is actually delivered to the prostatic urethra or is able to dwell there. Normal retrograde urethrograms seldom show much contrast in the prostatic urethra. Some urologists add cooled 2% lidocaine solution instilled through a catheter to their MIT protocols. Though intravesical lidocaine has been used as a local anesthetic for bladder procedures, it has not been suggested as a prostatic anesthetic [23, 24]. Until studies are done comparing procedures performed with topical lidocaine to those performed without, the true value of topical lidocaine is open for discussion in MIT protocols. That said, all catheter-based technologies [i.e. transurethral microwave thermotherapy of the prostate (TUMT)] call for some form of lidocaine gel instillation before placing the catheter. Likewise, most technologies for MIT involving endoscopes call for lidocaine topical gel as an added local anesthetic. In general, 10–30 mL of 2% lidocaine gel is instilled for a 5–20 min dwell time prior to the particular procedure. Cooling the gel may aid in the comfort of delivery [25]. There should rarely be any complication from transurethral lidocaine gel and system levels of lidocaine are not seen [26]. If indeed lidocaine gel is nothing more than a placebo, it may be a valuable placebo. Both patients and urologists are comforted by the idea of delivering an anesthetic through a "painless gel" rather than a needle, which is what is required for any of the prostate blocks that are discussed below. The current evidence, however, suggests topical local anesthesia to the urethra and prostate for MIT procedures probably is marginal in its true value, and clearly more expensive than water-soluble lubricant.

Prostate blocks

MIT options for the prostate that involve high-powered TUMT or rigid cystoscopy with either transurethral needle ablation, interstitial laser energy or laser evaporative/ablative techniques require more than simple topical lidocaine to the urethra. These endoscopic procedures must be performed with clear visualization of the prostatic urethra for optimal performance. Any sudden motion of the patient can jeopardize the procedure because of bleeding or patient discomfort. As such, all procedures were originally developed under general, regional (spinal) or intravenous sedation.

Urologists experienced with prostate blocks for prostate biopsy and transurethral needle injection technique began to develop techniques to block the posterior urethra and prostate in such a way that these procedures could be performed in the office setting. They were motivated to develop their own in-office protocols in the hope of saving overall costs without diminishing physician reimbursement. Standard techniques developed after evidence-based studies have not been established. Local anesthesia involving prostate blocks for MIT are still evolving. There are no studies comparing different in-office local anesthetic techniques for MIT. There are, however, articles on local prostate block for prostate procedures and much has been written on local anesthesia for prostate biopsy.

Moffat injected 10 mL of 1% lidocaine with epinephrine into each lobe of the prostate of 18 patients via a digitally-guided transperineal route using a 20G spinal

needle [27]. Then, using nothing more than topical lidocaine per urethra, he was able to dilate the urethra to 30F using sounds, and he then performed transurethral resection of the prostate (TURP) using a 28F resectoscope sheath. All procedures were performed in the operating room with anesthesia monitoring. Supplemental sedation was required in 10 of 18 patients. Remarkably, eight of the 18 patients had no intravenous sedation and no preoperative medications were given. Though this technique was seldom used, the fact remained that injection of lidocaine directly into the prostatic parenchyma must have anesthetic value if it allowed for a full TURP. Orandi followed up on this in 1984, describing multiple endoscopic procedures, including TURP, performed using transurethral lidocaine injected into the prostate and bladder neck via a specially devised endoscopic needle [28]. Supplemental oral and parenteral medications were used in his cases. The publication was presented as a "cost reducing idea." The technique similarly did not catch on. In 1993, Hugosson *et al.* published their results with transurethral incision of the prostate under local anesthesia [29]. Mepivacaine was injected transurethrally under direct vision into the bladder neck and posterior prostate to allow performance of a 6 o'clock incision of the prostate to treat men with lower urinary tract symptoms. The patients apparently received no supplemental preoperative or intraoperative medications. Twenty-eight of 30 patients claimed they would agree to the same procedure if another were needed. These examples suggest that local prostate block can allow for major endoscopic prostate procedures and that the block itself is responsible for pain control as opposed to oral or parenteral supplements.

Prostate blocks did not become common place, however, until the development of transrectal ultrasound-guided biopsy and ultrasound-guided periprostatic and intraprostatic blocks. Prior to transrectal prostate ultrasound, digitally-guided transrectal biopsy of the prostate was routinely performed with acceptable patient tolerance using no anesthetic. As template biopsies were developed in the prostate-specific antigen (PSA) era, along with saturation biopsy, local anesthetic techniques developed and showed that transrectal ultrasound-guided lidocaine for periprostatic block at the prostatic base could mitigate the discomfort of the biopsy [30–32]. Subsequent studies suggested that ultrasound-guided transrectal lidocaine at the apex worked just as well or better [33–36]. Transrectal intraprostatic injection of the prostate has been suggested as better than a periprostatic block for pain control [37]. Finally, a periprostatic and intraprostatic combination block may work best of all for transrectal ultrasound-guided biopsies [38, 39].

Armed with the knowledge that prostatic block could work in the operating room for transurethral resection procedures and that transrectal block worked well for prostate biopsies, urologists are adapting these technologies for office-based MIT of the prostate. The optimal technique is not yet known for any of the MIT modalities available today. As TURP took more than three decades to be considered a "gold standard," likewise it will likely take years before the new "gold standard" is born for MIT for male lower urinary tract symptoms due to BPH that can be performed in the office under local anesthesia.

Transrectal block for office-based minimally invasive treatment

Though most urologists are aware of and familiar with transrectal ultrasound-guided periprostatic and intraprostatic blocks for prostate biopsy, it should not be assumed that this will be optimal for transurethral MIT of the prostate. The incidence of febrile episodes after transrectal prostate biopsy may be increasing. Nam *et al.* found hospital admission rates after transrectal ultrasound-guided biopsy of the prostate increased fourfold from 1996 to 2005; 72% of these were admissions for infection [40]. Efforts should be made to ensure the rectal vault is empty of stool prior to biopsy and prophylactic antibiotics should be given.

The standard technique calls for ultrasound-guided injection of at least 5 mL of 1% lidocaine into the fat plane seen laterally at the base of the prostate, between the seminal vesical and rectum. On sagittal view, this appears as a "triangle," referred to by Jones as the "Mount Everest sign" (see Video 123.1) [30]. Each side must be injected. Alternatively, or at the same time, 5 mL of 1% lidocaine can be injected into the periapical fat, deep and lateral to the apex, between the prostate and rectum. On sagittal view, infiltration of anesthetic can be seen to separate a tissue plane that courses towards the base [33, 36]. The article by Berland and Jones in e-medicine fully describes transrectal periprostatic blocks and is a useful website. Using the same ultrasound-guided technique, intraprostatic anesthesia can be delivered by injecting 10 mL of lidocaine in increments in two to three sites within each lobe of the prostate from apex to base [37]. Though none of the transrectal local lidocaine blocks was developed for procedures other than biopsy, urologists have adapted them for MIT.

Kedia used a digitally-guided transrectal lidocaine block to perform interstitial laser coagulation of the prostate [41]. Other than transurethral lidocaine (a liquid and gel), patients received no oral or parenteral medications other than antibiotics. Turk has performed Evolve™ laser transurethral resection procedures in the office without any intravenous sedation, assisted in part by transrectal ultrasound-guided periprostatic block

[42]. However, it should be noted that he now favors a transurethral prostatic block. Meyer has performed many Prostiva™ radiofrequency procedures in the office using a transrectal periprostatic block with lidocaine from apex to base on each side, although oral analgesics and sedatives are used. He claims not to have terminated or abbreviated any procedures in over 300 cases (personal communication). Even TUMT procedures are being done with a transrectal block; transrectal ultrasound (which is needed to position the treatment catheter) is used to guide the lidocaine for a prostate block prior to the placement of the treatment catheter. Many TUMT procedures can be performed without a formal prostatic block. Members of our group are performing laser (Evolve and Green Light) procedures using transrectal ultrasound guided periprostatic and intraprostatic blocks with lidocaine. Good functional outcomes were recently presented at our State Urological Society Meeting [43].

Transperineal block

The transperineal block, though likely least utilized today to provide local anesthesia to the prostate, has the potential for resurgence if in-office MIT procedures continue to develop. Unlike the transrectal technique, the risk of infection should be lessened by allowing for a proper skin preparation and directing the needle to avoid contamination from the rectal mucosa.

A modern technique has been nicely described by Issa *et al.* [3] and Cohen and Steiner [44]. The patient is placed in the dorsolithotomy position with the perineum prepped and draped. A 27G needle may be used to anesthetize the entry site in the perineum above the perineal body. A 22G spinal needle (3.5 inches long) is attached to a 20-mL Luer Lock syringe containing the anesthetic (i.e. 1% lidocaine). The needle is directed into the midline, deep to the apex of the prostate under transrectal digital guidance. The anesthetic solution is infiltrated, defining a plane between rectum and prostate that may be palpated as the rectum is elevated from the prostate. At least 10 mL of the anesthetic solution is injected deep to the prostate on the right and then the left, from apex to base. This should deliver anesthetic levels similar to transrectal anesthetic technique. The needle need not be removed from its insertion site as injections occur, as aspirating periodically ensures that the injection is not into venous spaces. Interstitial laser coagulation (ILC) therapy has been successfully performed without the need for intravenous sedation using the transperineal periprostatic block [3].

A simple technique for transperineal digitally-guided block of the urethrosphincteric region has been recently described by Al-Hunayan *et al.* [45]. They injected 5–10 mL of lidocaine into the region just caudad to the apex of the prostate, above the rectum on each side of the midline. Their technique showed improved comfort with rigid cystoscopy over lidocaine per urethra (Figure 123.2). Likewise, transurethral needle ablation of the prostate has been similarly performed [46].

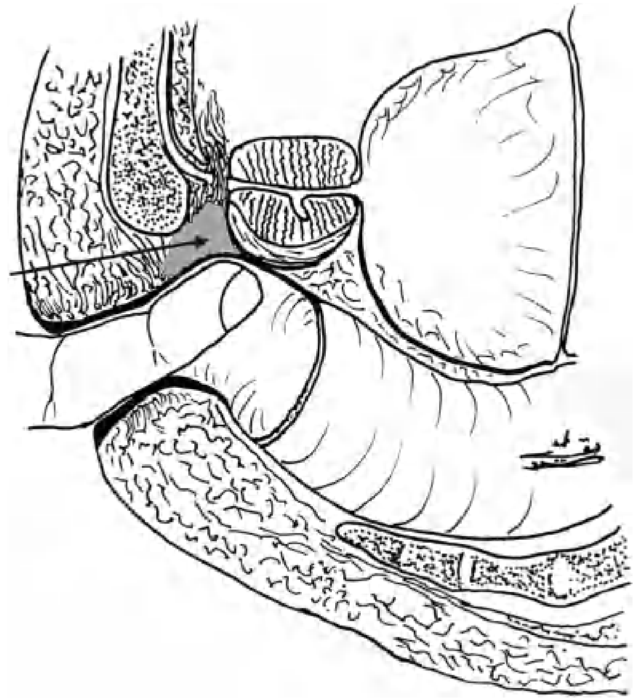

Figure 123.2 Digital guidance for transperineal prostatic block. This depicts the infiltration of lidocaine (gray area indicated by arrow) in a location bounded by the rectum posteriorly, the rhabdosphincter anteromedially, and the apex of the prostate superiorly (reproduced with permission of Dr Al-Hunayan and Springer Science Business Media [45]).

As mentioned earlier, TURP has been performed using a transperineal intraprostatic block without the need for intravenous sedation [27]. The transperineal route could also be very easily used to perform intraprostatic injection of anesthesia for MIT. Using an anesthetic agent that contains epinephrine could potentially mitigate bleeding for transurethral procedures. Though not studied specifically for MIT, this route also would have an added advantage over the transurethral intraprostatic injections in that the prostatic lumen could be avoided by targeting the needle laterally, thus minimizing potential bleeding from the needle entrance site in the prostatic urethral lumen. Clearly, if the procedure is planned in the office, the MIT modality itself should already be proven to minimize the risk of bleeding.

Transurethral prostate blocks

Since originally described by Orandi, transurethral prostate blocks have been reinvented by urologists in order

to perform local MIT of the prostate in the office setting. The technique can easily be performed by any urologist using a flexible injection catheter passed via the cystoscope. The patient is prepared for rigid cystoscopy in the lithotomy position. Oral agents, both analgesics and sedatives, can be helpful. The cystoscope is passed and the prostatic lumen and bladder are examined. An injection catheter (Bard Contigen, Cook Urologic, Storz reusable, etc.) can then be used to inject 3–5 mL of an anesthetic solution (i.e. lidocaine) into the bladder neck at the 5 and 7 o'clock positions. The cystoscope is then moved distally to view the prostatic lobes which are then anesthetized by injecting at the 3 and 9 o'clock positions with additional lidocaine. Injections can be repeated in different areas if needed for longer or larger glands (see Video 123.2). Patient selection is important. The transurethral block also avoids the rectum and its potential for infection. Using this technique, urologists have performed interstitial laser coagulation, transurethral needle ablation, and laser prostatectomies, including Green Light and Evolve laser prostatectomies. TUMT time can be diminished by transurethral mepivacaine with epinephrine, with improved comfort [14]. These procedures have been performed in the office without the need for an intravenous line or special monitoring, other than close observation and periodic measurement of vital signs. Published studies regarding outcomes are lacking. Though members of our group have used this technique, they have found bleeding occasionally problematic for laser ablation procedures and now prefer the transrectal technique previously mentioned.

Pudendal nerve block

Pudendal nerve block is mentioned as it may have endourologic application for the lower urinary tract, and it is an anesthetic that can be delivered by the urologist. Mahmood Hai (Dearborn, MI, USA)probably has the world's greatest urological experience with pudendal nerve block in men, a technique he developed from his knowledge of pudendal blocks in women. In his surgery center he has performed outpatient photoselective vaporization of the prostate on over 1000 patients. His technique involves a transperineal approach. Two 20G 12-cm disposable spinal needles are attached to 20-mL syringes loaded with a 0.5% lidocaine solution. For right-handed urologists, the left index finger is inserted rectally to identify the landmarks; the ischial tuberosity, ischial spine, and sacral spinous ligaments. The needle is inserted perpendicular to the skin about 2.5 cm posteromedial to the ischial tuberosity. The needle is slowly advanced through the ischial rectal fossa towards the ischial spine, guided by the rectal finger. As the needle hits the spine, it is pushed posterior to it by the guiding finger. This places the bevel of the needle at the beginning of Alcock's canal. After attempted aspiration in two planes to make sure the needle is not in a blood vessel, 5 mL of the solution is injected. In most instances, the wheel produced can be palpated by the rectal finger. The needle is advanced about 0.5 cm and the remaining 5 mL are injected. The needle is withdrawn and firm pressure is applied over the area by the rectal finger for 1–2 min. A similar procedure is done on the opposite side (see Video 123.3). The anesthetic should be effective within 5 min and photoselective vaporization of the prostate can be started (see Video 123.3).

This form of anesthesia is not one that should be considered in the office setting without an intravenous line and proper monitoring. There is a potential for bleeding and nerve damage, as can rarely occur with any regional nerve block. Dr Hai does have an intravenous line for sedation, monitored by an anesthesiologist. Nevertheless, it is worthwhile being aware of this technique as it represents a locoregional anesthetic which urologists can and are being trained to perform. More study will be needed before we know the true risk-to-benefit ratio compared to other anesthetic techniques.

Conclusions

This may be a new era in urologic practice; treating more patients in the office with MIT of the prostate. As technologies evolve, so will the consensus of "best practice" regarding office-based local anesthesia. Studies are sorely lacking that compare one anesthetic technique to another. The potential for tremendous cost savings still exists if the hospital and anesthesiology charges can be avoided by office-based therapy. Office-based therapies, however, must be proven to be just as effective with comparable long-term result. Urologists interested in pursuing office-based procedures under local anesthesia should realize that the information presented in this chapter will hopefully be dated in 5 years, as more outcome and comparative studies are done so that evidence-based recommendations can be made on the "best practice" of office-based anesthesia for the MIT of the prostate. It is likely that combining the techniques described in this chapter will result in improved local anesthesia for MIT of the prostate. Finally, without question, new technologies and techniques will continue to arise to treat lower urinary tract symptoms due to BPH. Office-based therapy has a great potential to provide for major cost savings as long as the urologist finds it economically viable to pursue such care in the office. Regardless, all urologists should be aware of the importance of minimizing anesthetic risks and cost for MIT of the prostate. Local anesthetic techniques may diminish anesthesia needs, time of recovery, and costs.

These cost savings may also be realized in the hospital or ambulatory surgery center setting. Such techniques

might be applicable to more invasive hospital-based procedures, such as TURP in high-risk individuals or the very elderly, where close anesthetic monitoring is always required. The anesthetic risks may possibly be diminished by the use of local anesthetics. Similarly, though MIT of the prostate may be easy to perform in the office, caution and proper monitoring are always needed in high-risk or very elderly patients. Judgment is always required in selecting candidates for office-based MIT of the prostate using local anesthesia.

CHAPTER 124
Microwave Therapy

Stavros Gravas
Department of Urology, University of Thessaly, Larissa, Greece

Introduction

The application of heat for the management of numerous complaints and diseases is a well-known in medicine. However, it was not until the late 1980s that treatment of the prostate used microwaves and radiowaves to produce heat delivered either rectally or transurethrally [1]. Hyperthermia, defined as a temporary heating of the body or parts thereof to temperatures (>40–45°C) not resulting in denaturation of proteins, was the first technique to be developed. This has developed into thermotherapy, in which temperatures range from 45 to 60°C, resulting in effective necrosis [1]. Many different energy sources are used to produce heat, but application of microwave technology, solely through the transurethral route, has gained a firm position in currentl ablative methods due to the excellent clinical results obtained in the treatment of lower urinary tract symptoms (LUTS) due to benign prostatic hyperplasia (BPH).

Principles

Microwave thermotherapy of the prostate involves the emission of microwave radiation through an intarurethral antenna to deliver heat within the prostate, with the goal of destroying tissue by achieving temperatures that exceed the cytotoxic threshold. The extent of the necrosis is governed by two physical variables: intraprostatic temperature and duration of heat exposure [2]. If the intraprostatic temperatures do not get high enough, the treatment needs to be for longer, and *vice versa*.

Microwaves are electromagnetic radiation with an oscillating electrical and magnetic field in the range of 300–3000 MHz. Microwaves follow the basic physical properties of electromagnetic radiation transmission in free space or in a medium, and are reflected, deflected, or scattered at the interfaces of two media with different impedances. The heat is produced when the microwaves are absorbed by the tissue, and arises mainly by two processes: electric dipoles, e.g. water molecules, which oscillate in the field; and electric charge carriers, e.g. ions, which move back and forth in the field. These movements transfer energy to the tissue in the form of heat.

The penetration of microwaves is usually defined as the tissue depth at which the strength of the microwave field has decreased to 37% of its original value [3]. Penetration is deeper in low-water content tissue (fat) than in high-water content tissue (muscle, prostate), because the water molecule is a primary absorption target [4]. It also depends on the wave frequency: The higher the frequency, the shorter the wavelength and thus the smaller the penetration depth in the tissue. Ideally, the penetration in water-rich tissues is approximately 100 mm at 100 MHz, while at a frequency of 2450 MHz the penetration is reduced to approximately 10 mm. Another important physical principle of microwave-induced heat distribution is that it is distance dependent: the farther the target from the microwave applicator, the lower its temperature. This

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

temperature decrease is due to the declining microwave penetration and cooling effect of blood flow. Based on this principle, it is obvious that the peak temperature will occur at the mucosa adjacent to the applicator. In order to move the peak of the heat distribution into the prostate and to avoid injury to adjacent tissue, a surface coolant was introduced to reduce the temperature in the vicinity of the applicator.

The transurethral microwave thermotherapy (TUMT) devices, used for the management of symptomatic BPH, consist of a power oscillator, urethral cooling system, temperature monitoring system, and control console. The energy is delivered to the target tissue by the microwave antenna through a transurethral catheter, while the treatment is controlled by a computer software system. The transrectal route was proved problematic and has been abandoned; it heated the periphery and not the transition zone of the prostate, appropriate and stable positioning of the probe was difficult, and long-term results were disappointing.

Experimental studies: mechanism of action

Microwave delivery systems designed to heat prostatic tissue were initially tested *in vivo* in a dog model [5, 6]. In addition, researchers evaluated the histopathologic alterations in the canine prostate after hyperthermia and thermotherapy [7, 8]. All these pioneering animal studies have provided the experimental basis for many of the principles applied in the treatment of humans and have shown the method to be feasible and safe. Studies on the human application of thermotherapy (temperature > 45°C) were started in the early 1990s by Devonec *et al*., who treated patients with symptomatic BPH during 50-min sessions, which gave mild relief [9].

The most recent experimental studies have focused on understanding the mechanism of microwave thermotherapy and the factors that can influence the treatment outcome, in order to eventually individualize the therapy and optimize the clinical result.

It has been shown that heating to in excess of 45°C results in coagulation necrosis [10], following the general pattern of burn wounds that is characterized by inflammatory reactions that lead to a rapidly developed necrosis and edema [11]. Microthrombi will occlude vessels and the blood flow will not be adequate for cell survival, and even less so for repair. At the cellular level, heat causes thermal inactivation of enzymes and structural proteins, and rupture of cell membranes. Cell death occurs when the thermal damage is so severe that repair mechanisms (replacement of enzyme proteins and synthesis of new membranes) are insufficient or when the DNA and RNA transcription enzymes that mediate the repair mechanisms are destroyed [12–14].

In one of the earliest studies, Moritz and Henriques showed that the thermal damage to pig skin exposed to 45°C for 7h was approximately the same as that following exposure to 50°C for 5min [15]. Cell survival studies on mammalian cells confirm the relationship in the temperature range used for microwave thermotherapy: 43–57°C [12]. However, different cell types and tissues may have different heat sensitivity, reflecting differences at the sub-cellular level: a change of only a few amino acids in proteins can make them more or less heat resistant [12]. A significant finding is that in order to maintain the same biologic isoeffect for a given cell line, the duration of heating should be increased by a factor of about 2 (R value) if the temperature is decreased by 1°C [12].

It was reported that apoptosis was observed in a variety of cell systems at temperatures lower than those inducing necrosis [16]. In the periphery where the thermal exposure is lower, apoptosis may be the contributing cell kill mechanism [11, 17]. Brehmer and Svensson investigated the feasibility of using heat to induce apoptosis in human prostatic stromal cells. Cell cultures were exposed to 47°C for 1h and the most extensive apoptosis (in 76% of the cells) was noted 24h after heat treatment [17].

It has also been proposed that induced necrosis disrupts periurethral alpha-adrenergic receptors, reflecting in denervation of the smooth muscle cells [18]. These findings may be responsible for the increased urinary flow after TUMT. It has been demonstrated that TUMT increases the sensory threshold (evoked by electrical stimulation) in the posterior urethra by 30% or greater, resulting in the alleviation of irritative symptoms [19].

Factors affecting thermotherapy of the prostate

Thermotherapy of the prostate is mainly affected by the three main steps that control the course of the treatment: (1) generation of microwave power, delivery of the energy to the tissue, and generation of heat through absorption of the applied microwave energy; (2) dispersion of heat by conduction in the tissue; and (3) loss of heat through blood flow.

Generation, delivery, and absorption of microwave energy

The first step depends on the operating characteristics of the TUMT device and the antenna used to deliver the energy. Several TUMT devices are available and differ in frequency of the generator and design of the antenna. While it is known that microwave penetration depends on the wave frequency, it has also been demonstrated that the prostate is heated in the vicinity of the antenna where the electromagnetic field is disturbed; thus the

penetration depth of the microwave or heat is independent of the frequency within the broad interval from 680 to 2450 MHz [20]. Therefore, the range of coagulation necrosis achieved by a standard TUMT with an applicator emitting 900-MHz microwaves is similar to that obtained with 2450-MHz microwaves. Since the vast majority of thermotherapy devices use 915 or 1296-MHz microwaves, at a conceptual level these TUMT devices do not substantially differ and should therefore can be evaluated as one group.

Knowledge of the spatial distribution of the heat in the prostate is of paramount importance in order to achieve ablation of the transition zone and avoid undesired tissue injuries due to uncontrolled radiation. Therefore, the delineation of the radial and axial emission characteristics of antennas used to deliver energy to the prostate plays a key role in the choice of the appropriate antenna for a specific patient. Bolmsjö *et al.* performed an excellent study comparing the heat characteristics of three microwave antennas in a tissue-equivalent phantom prostate [21]. This phantom model absorbed only a part of the emitted energy, and this varied from 13% to 21% depending on the type of the antenna. It was suggested that the antenna design affects the heating pattern more than does the wave frequency [21].

Another operating characteristic of TUMT devices is the software protocol used to emit energy. Initial lower energy thermotherapy (LE-TUMT) protocols were clinically evaluated to confirm their safety and efficacy [22–24]. High-energy thermotherapy (HE-TUMT) was developed in accordance with the hypothesis that more energy should create higher temperatures and achieve a better clinical outcome. The higher-energy protocols result in a mean increase in the total energy delivered to the prostate of 40%, and in intraprostatic temperatures ranging between 45 and 80°C, which leads to coagulative necrosis that can create a prostatic cavity. It is logical that the more energy that is delivered, the more pronounced the thermoablative effect [25].

Another modification to the treatment protocols has been the heat-shock strategy in order to overcome the adaptation of the vessels to the slow increase of intraprostatic temperature, leading to resistance to the heat effects. The heat-shock strategy is characterized by a rapid build-up in power/temperatures that causes immediate vascular thromboses, resulting theoretically in a similar or better clinical outcome in a shorter duration of treatment [26].

Dispersion of heat by conduction in the tissue

The second step is determined by the tissue composition. The proportion of the various components of the prostate [epithelium-to-stromal ratio (E/S)] differs for each individual and this heterogeneity of the prostate histopathology has been suggested as the "intrinsic" factor responsible for the variability in clinical outcome, as each of the component reacts differently to microwaves. Microscopic examination has shown that acinar cells appear to be more resistant to heat than smooth muscle cells when exposed to the same temperature [27]. D'Ancona *et al*. correlated histologic findings from biopsy material with the therapeutic response to TUMT. No significant difference could be demonstrated for the tissue ratio between good and poor responders, despite the observation of a trend towards a lower E/S ratio in poor responders [28]. Furthermore, a large prostate has reported to be a favorable predictive factor for TUMT, because large prostatic volume appear to serve as a physical barrier to temperature distribution outside the gland, mainly to the rectal wall [25].

Blood flow

The third step is affected by the spatial and temporal variations of blood flow that affect thermotherapy outcomes and contribute to the lack of uniformity in clinical results [29]. Prostatic blood flow acts as a natural coolant, decreasing the intraprostatic temperature and delaying the coagulation mechanism [30]. The removal of thermal energy through the circulating blood (the theory of the "heat sink") affects the local effective temperature. Blood flow changes dynamically as treatment continues: at the beginning of the treatment, an increase in blood flow is usually seen, probably reflecting the vasodilation caused by the elevated temperature. Wagrell *et al*., using positron emission tomography (PET) to measure the intraprostatic blood flow, noted a rapid increase in blood flow up to 100% during the first 25–30 min of the treatment [31]. Towards the end of the treatment, blood flow decreases, most probably due to the occurrence of microthrombosis, with consequent capture of the heat in the exposed tissue causing faster coagulation necrosis. Floratos *et al*. studied the baseline intraprostatic vascularization using three-dimensional contrast-enhanced power-flow Doppler (3D-CE-PFD) prostate ultrasonography in a group of 22 patients treated with TUMT [32]. It was concluded that the baseline intraprostatic vascularization, documented by CE-PFD studies, has no predictive value for the efficacy of TUMT. It seems that "static" baseline blood flow does not reflect the "dynamic" thermoregulatory role of blood flow during treatment [32].

Optimal thermal treatment by temperature monitoring

Continuous monitoring of spatiotemporal intraprostatic temperature distribution would contribute to a better

understanding of the basic mechanism of thermotherapy and tailoring of the treatment as well. Experimental studies have been conducted in order to evaluate the thermal mapping of the prostate, with the goal of understanding how to heat prostate. Several intraprostatic thermometry techniques have been proposed, including invasive and noninvasive methods. Interstitial thermal mapping in canine and human prostates using thermocouple arrays has been reported, but the invasive nature of the method makes it less attractive [9, 33, 34]. A less invasive method has been introduced and is commercially available [ProstaLund feedback treatment (PLFT)] [35]. PLFT continuously monitors the intraprostatic temperature using three sensors in a row on the needle-like temperature probe that protrudes through the catheter into one of the lateral prostatic lobes. Temperatures from the tip, mid, and apex of the prostate are considered to be recorded, allowing the operator to adjust manually the microwave power according to the actual measurements. The measured temperature is used to calculate the amount of necrotized tissue, by using a combination of the bioheat equation and cell survival data of thermal exposure [36].

Microwave radiometry thermometry is based on the thermal noise power, i.e. the electromagnetic radiation emitted by a given body whose temperature is raised. It has been clinically evaluated but it appears to have limited spatial resolution [37]. Magnetic resonance imaging (MRI) is temperature sensitive and this allows thermal mapping at the time of the treatment. Different MRI techniques have been used, including water diffusion, coefficient, T1 relaxation time, proton resonance frequency, and MR spectroscopic imaging [38]. Results suggest that MRI is a promising method because it offers good spatial localization and sufficient temperature sensitivity [39]. Ultrasound thermometry is another promising modality that is based on temperature-dependent acoustic tissue parameters, such as sound velocity, attenuation, back scattered power, and thermal expansion [40, 41].

The extent of tissue debulking due to coagulation necrosis may play a significant role in TUMT clinical outcome in terms of response and durability. Quantification in realtime of the amount of tissue ablated will allow treatment to be adjusted for each individual patient, and indicate when the desired volume has been destroyed and thermotherapy should be stopped. Bolmsjö *et al*. developed a cell-kill (i.e. tissue death) model to estimate the amount of the necrotized tissue, using both Henrique's damage integral and Jung's compartment model in a computer program [35]. In 22 patients treated with TUMT, the authors reported that cell kill was calculated with reasonable accuracy compared to transrectal ultrasound (TRUS)-determined volume reduction 3 months after TUMT. This cell-kill model has been integrated into the ProstaLund treatment software. Nordling *et al*. concluded from a prospective randomized multicenter study on 100 patients treated with PLFT that the calculated cell kill was a valid and good predictor to determine when to stop treatment [42].

Gadolinium-enhanced MRI has been used to determine the extent and pattern of coagulation necrosis caused by TUMT. Osman *et al*. treated 13 patients using the Targis device (Urologix, Minneapolis, MN, USA) and performed a post-treatment MRI [43]. Necrotic tissue presented as a perfusion defect that accurately correlated with the prostatic tissues exposed to temperatures of 45°C or greater for at least 45 min. Huidoro *et al*. investigated the intraprostatic heat distribution and the relation to histopathology, MRI, and cell-kill calculations using the CoreTherm TUMT device (ProstaLund, Lund, Sweden). Microwave treatment caused necrosis of the prostate, bladder neck, and urethral mucosa, and the tissue necrosis assessed by pathology, MRI, and cell-kill calculation was comparable [44]. Recently, Vesely *et al*. confirmed that the CoreTherm device causes distinct intraprostatic necrosis detectable by MRI and reliably predicted by the cell-kill calculation. Perfusion of the prostate before the treatment was not shown to have any impact on treatment parameters [45]. On the other hand, using diffusion-weighted MRI before treatment, it was found that the apparent diffusion coefficient (ADC) value, which characterizes the microstructure of the prostate, correlated strongly with the treatment parameters. More specifically, prostates with a lower ADC, and thus a more complex structure, needed a significantly higher amount of energy and a longer time to achieve a desirable amount of necrosis [45].

Translation into clinical practice: TUMT devices

Based on the described principles of microwave thermotherapy, several devices operating at either 915 MHz or 1296 MHz with different microwave antenna designs, cooling systems, treatment times, and monitoring of TUMT effect have been introduced. The main players in the field of microwave thermotherapy are the Prostatron® device (Urologix), Targis® (Urologix), CoreTherm® (ProstaLund), the TMx-2000® (TherMatrx Inc, Northbrook, IL, USA).

Prostatron first used the first-generation, low-energy Prostasoft 2.0 software, followed by the Prostasoft 2.5 high-energy software. Later, 30-min high-energy software was developed, the Prostasoft 3.5 protocol. The CoreTherm system provides intraprostatic temperature monitoring. The measured temperature is used for real-time calculation of the amount of necrotized tissue,

using a combination of the bioheat equation and cell survival data of thermal exposure. Consequently, the system allows tailoring of treatment to the needs of each patient. Targis is a high-energy cooled thermotherapy system. In addition, a third-generation Urologix system, the Cooled ThermoCath (CTC), which uses a 28.5-min treatment at higher temperatures, has also been developed. The TherMatrx TMX-2000 differs from other available microwave device systems in that it lacks a cooling system and uses a lower wattage.

Efficacy of TUMT

Numerous studies have been published presenting the clinical results from the application of TUMT. These studies have used different devices with different treatment protocols, and have had different follow-up periods. Generally, studies on BPH treatment use the improvement in maximum urinary flow rate (Qmax) and changes in International Prostate Symptom Score (IPSS) as the objective and subjective outcome measures, respectively. The objective and subjective improvements of the initial LE-TUMT protocols have been proven in prospective randomized sham-controlled studies [46–48]. In addition, HE-TUMT-protocols were developed, further reinforcing the meaningful response to therapy being greater than the sham effect of instrumentation. A systematic review analyzed data from 850 participants (523 treated with TUMT and 327 sham controls) in seven randomized trials [49]. The TUMT group had greater improvement in symptom scores than the sham control group. The pooled mean IPSS for men undergoing TUMT decreased by 50% in 3–6 months (21.4–10.8) versus 41% (21.3–12.6) in the men undergoing sham treatment. Similarly, Qmax improved slightly more following TUMT compared to sham treatment: 1.7 mL/s (95% CI 1.0–2.3). The pooled mean Qmax for patients undergoing TUMT increased 43% (from 8.1 mL/s to 11.6 mL/s) versus 11% (from 8.7 mL/s to 9.7 mL/s) in men undergoing sham treatment [49].

In the evaluation of minimally invasive treatments for BPH, the results of each new therapy need to be compared with those obtained with conventional surgical procedures, namely TURP. Recently, a Cochrane systematic review of all available randomized controlled trials (RCTs) on TUMT attempted to quantify its therapeutic efficacy [49] (Table 124.1). Treatment was with different TUMT devices and software, including Prostatron (Prostatsoft 2.0 and 2.5) and ProstaLund Feedback. Overall, of 540 patients 322 were randomized To TUMP and 218 to TURP in the six eligible randomized studies. Weighted mean differences (WMD) were calculated with 95% CI for the between treatment differences in pooled means. TUMT was somewhat less effective than TURP in reducing LUTS. The pooled mean symptom score for men undergoing TUMT decreased 65% in 12 months (19.4 to 6.7) compared with 77% (19.6 to 4.5) in men undergoing TURP, with a WMD for the symptom score of –1.83 (–3.09 to –0.58), favoring TURP [49]. TURP achieved a greater improvement in Qmax (119%) than TUMT (70%), and the calculated WMD was 5.44 (4.22–6.51) mL/s in favor of resection at the 12-month follow-up [49]. The mean Qmax after TUMT was generally less than 15 mL/s: only two studies reported a mean Qmax following TUMT greater than 15 mL/s, while five studies reported that TURP achieved a mean Qmax greater than 15 mL/s. No statistically significant difference for improving urinary symptom scores or peak urinary flow could be detected between the different devices [49].

Similar clinical outcomes have been reported Kayne *et al.* in a recent meta-analysis of the available RCTs

comparing HE-TUMT with TURP [50]. This meta-analysis calculated a summary mean difference of continuous variables, including IPSS, Qmax, and postvoid residual (PVR) for 458 patients. Twelve months after treatment, changes in Qmax ($P < .001$), IPSS ($P = .01$), and PVR ($P = .02$) were more significant for TURP than TUMT (Table 124.1). Interestingly, when data were stratified according to the TUMT device, the CoreTherm device (PLFT system) demonstrated the most significant improvements in subjective and objective criteria [50].

Gravas *et al*. performed a pooled analysis of three studies of the ProstaLund Feedback TUMT device with 12-month follow-up [51]. Two randomized studies comparing PLFT to TURP and an open-label study with no comparative group were combined. Inclusion and exclusion criteria for the three studies were identical and this fact reduced any selection bias. A total of 248 patients were studied; 183 were treated with the PLFT and 65 with TURP. The responder rates were 85.3% and 85.9% in the PLFT and TURP groups, respectively [51]. One-sided 95% CI analysis showed noninferiority of PLFT as compared to TURP. A "responder" was defined as a patient who following treatment had an IPSS of 7 or less, and/or 50% or greater improvement in IPSS from baseline, and/or a Qmax of 15 mL/s or more, and/or 50% or greater improvement in Qmax from baseline [51]. In addition, there was a marked decrease from a mean IPSS of 20.9 at baseline to 6.4 at 12 months after TUMT, which is a decrease of 69% compared to baseline (Table 124.1). In the TURP group, mean IPSS was decreased from 20.7 at baseline to 7.1 at the 12-month visit (a 66% change). The one-sided CI (95%) for the ratio of IPSS between the PLFT and TURP groups suggested noninferiority of PLFT compared to TURP treatment. In the PLFT group, the mean Qmax improved from 7.7 mL/s at baseline to 16.1 mL/s at 12-month follow-up, corresponding to a 109% increase (Table 124.1). In the TURP group, Qmax increased from a mean value of 7.5 mL/s at baseline to 18.6 mL/s at the end of treatment (a 148% change). However, although both treatment modalities significantly improved Qmax, one-sided 95% CI analysis showed that noninferiority of PLFT as compared to TURP did not reach the predetermined level. This pooled analysis indicated that PLFT appears to have an efficacy that in terms of IPSS and responder rate is non-inferior to TURP [51].

Patients in urinary retention

The indication for microwave treatment has gradually changed from patients with solely irritative symptoms to now include patients with evident obstructive elements and patients in urinary retention. Men in retention represent a specific group of benign prostatic obstruction (BPO) patients; in general, they are at increased risk of perioperative morbidity and mortality and present a lower response to any treatment that resolves obstruction [52]. In the past, urinary retention was considered as a contraindication for TUMT but today urologists feel more confident to offer this minimally invasive option to patients in retention due to the advanced devices and treatment protocols.

Level 2b evidence studies have reported a success rate for TUMT (defined as the percentage of patients who regained their ability to void spontaneously) ranging from 80% to 93% (Table 124.2) [53–58]. However, these studies had a very short follow-up (≤12 months), making it difficult to estimate the durability of TUMT outcome in patients with retention. Floratos *et al*. estimated the 1-year retreatment rate to be 25% [59]. In a study of 213 patients (45 in retention) treated with the Prostasoft 3.5 and followed-up for up to 5 years, it was found that the treatment failure rate was 37.8% in the retention group [60]. The cumulative risk at 5 years was 58.8% for patients in retention, while the corresponding risk for patients without retention was 42.3% ($P = .03$), indicating that the risk of retreatment is higher for patients in retention prior to TUMT [60].

Table 124.2 Efficacy of transurethral microwave thermotherapy on patients in retention.

TUMT versus medical therapy

The position of TUMT versus medical therapy for the management of LUTS with BPO has also been evaluated by Djavan *et al*. in an RCT of 103 patients treated with either targeted TUMT or with terazosin [61]. The mean IPSS improved significantly from baseline by 6 months in both groups, but men treated with TUMT had significantly greater symptom relief as measured by the IPSS (WMD –4.20, 95% CI –5.25 to –3.15) and improvement in peak urinary flow (WMD 2.30 mL/s, 95% CI 1.47–3.13). The percentage of TUMT patients having a 50% or greater increase in Qmax and IPSS at 6 months (64.7% and 78.4%, respectively) markedly exceeded that in the terazosin group (9.6% and 32.7%, respectively). In an update of the study on TUMT versus terazosin, patients had been followed-up for 18 months [62]. The subjective and objective improvement observed at 6 months was maintained at 18 months, and was significantly greater in the TUMT group compared to the terazosin group (by 35% and 22%, respectively). By 18 months, 21 patients had failed terazosin therapy: in 13 it was ineffective and in eight because of side effects. Three patients failed TUMT by 18 months and proceeded to surgery [62]. The actuarial rate of treatment failure at 18 months in the terazosin group (41%) significantly exceeded that of the TUMT group (5.9%), resulting in a significantly lower risk of retreatment for men treated with TUMT (RR 0.12, 95% CI 0.04–0.38; RD –0.43, 95% CI –0.27 to –0.59).

Durability

Besides favorable short-term outcome, durability of long-term improvements is prerequisite for acceptance of TUMT and therefore subjected to investigation. TUMT has been criticized for the lack of high-quality studies on its durability. In general, most of the studies vary in follow-up duration and are characterized by a significant attrition rate. Consequently, less than half of the initial group of patients treated is analyzed at 4–5 years in terms of Qmax and IPSS, and these patients are likely to represent the best responders. Reviewing the randomized long-term trials comparing HE-TUMT to TURP, it is found that improvement in urinary flow rate remains stable at 6 and 12 months follow-up, but there is some deterioration after 2.5 years [63–65]. The maximum improvement in IPSS is obtained 3 months after treatment and the subjective improvement remains significant and durable for more than 30 months after TUMT, despite a slight increase in IPSS. A similar trend is observed for patients treated with TURP, but the magnitude of improvement is greater. Table 124.3 summarizes the long-term results from RCTs and a pooled analysis of TUMT studies [63–66].

Retreatment rate, defined as the percentage of patients undergoing any additional therapy for the primary treatment failure, represents an important parameter for the evaluation of treatment durability. Retreatment of TUMT is related to treatment failure whereas retreatment of TURP is related to complications of resection.

LE-TUMT has shown disappointing results in terms of durability, with several studies reporting a retreatment rate of up to 84.4% after 5-year follow-up [67–69]. Reported retreatment rates after HE- TUMT range from 19.8% to 29.3%, but with different mean follow-up durations (from 30 to 60 months) [63, 64, 66, 70]. In the systematic review of randomized trials described above, Hoffman *et al*. estimated the retreatment rate due to treatment failure, expressed as the number of events per person per year of follow-up [49]. It was found that TUMT patients (7.54 events/person-years) were more likely than TURP patients (1.05/100 person-years) to

require additional treatment for BPH symptoms, while in contrast the retreatment rate for strictures (meatal, urethral or bladder neck) was found to be 5.85/100 person-years and 0.63/100 person-years for the TURP and TUMT groups, respectively [49].

Tsai *et al.* reported the 5-year results of a prospective randomized multicenter study comparing TUMT with the CoreTherm device (PLFT; ProstaLund) to TURP [67]. No statistically significant differences were found between the two treatment groups in Qmax and IPSS at 60 months. In the TUMT group, 10% needed additional treatment versus 4.3% in the TURP arm. These data suggest that at 5 years, clinical results obtained with PLFT TUMT were comparable to those seen after TURP [67].

TUMT as an outpatient procedure: tolerability, safety, and morbidity

Unlike TUMT, for TURP spinal or general anesthesia is a prerequisite. TUMT treatments are usually well tolerated by patients. Perception of discomfort varies from a mild feeling of perineal warmth and a mild urge to urinate to occasional significant discomfort. Distraction and reassurance are usually enough, but momentary interruption of microwave emission may be useful in those cases where major discomfort is experienced. In contrast to lower-energy protocols, pain medication needs to be administered in a higher number of patients prior to or during HE-TUMT [71]. In a Food and Drug Administration (FDA) trial, regional and general anesthesia was required in 32% of patients, oral sedation in 19%, and parenteral sedation in 12% [72]. The need for sedoanalgesics in every patient has been questioned. A randomized comparison of topical urethral anesthesia alone versus topical anesthesia with adjunctive intravenous sedoanalgesia showed that the former was well tolerated by patients, thus avoiding the risks of sedoanalgesics during treatment [73].

Schelin studied the effects of intraprostatic and periprostatic injection of mepivacaine epinephrine prior to TUMT [74]. He concluded that the administration of mepivacaine epinephrine seems to have beneficial effect on treatment time, required energy, and intraprostatic blood flow, and improves patient comfort [74]. Similarly, Knutson *et al*. found that intraprostatic injection of mepivacaine epinephrine results in a significant decrease in the number of patients requiring intravenous analgesia (11% of the intraprostatic injections group vs 70% of patients without intraprostatic injection). In addition, it was concluded that, besides increased patient comfort, this technique may also reduce the treatment time without decreasing treatment success, thereby making PLFT treatment more manageable in outpatient practice [75].

Larson *et al.* performed a retrospective study to investigate the occurrence of adverse blood pressure events during TUMT using all six FDA-approved devices with different anesthetic/analgesic protocols [76]. Approximately half of the patients undergoing TUMT showed marked and acute blood pressure increases. The stratified results showed variability among the TUMT devices used for treatment. The mechanisms responsible for these surges and the causes of these variations could not be identified. These data indicate that blood pressure should be monitored and, treatment adjusted, and antihypertensive medications continued during all TUMT procedures [76].

Pooled data of the published randomized studies comparing TUMT and TURP regarding morbidity indicate that the main advantage of TUMT is its low morbidity [49, 77, 78] (Table 124.4). Prolonged catheterization, dysuria or urgency, and urinary retention were the most frequent adverse events after TUMT. For patients treated with TURP, the mean length of hospitalization and catheterization time was 4.0 days and 3.6 days, respectively, and the corresponding mean values for TUMT were 0 days and 13.7 days. The incidence of hematuria, clot retention, transfusions, and TUR syndrome was reported to be significantly lower for TUMT than for TURP. The impact of TUMT on sexual function in terms of erectile dysfunction and retrograde ejaculation has also been studied in comparison to TURP, with pooled data favoring TUMT. The surgical retreatment for urethral strictures and/or bladder neck contracture has also been found to be significantly higher for TURP (5.85/100 person-years) than for TUMT (0.63/100 person-years), with a relative hazard of 9.76. [49].

A variety of other rare but reported complications following TURP occur. These includes, but are not limited to, bladder perforation, urethrovesical fistula, and emphysematous, prostatic abscess. The FDA has published safety recommendations for the use of TUMT devices [79].

Consequently, TUMT is considered as a true outpatient procedure due to its low morbidity and lack of need for any anesthesia (spinal or general), and thus represents an excellent option for patients with high operative risk [80].

Outcome predictors

Although thermotherapy is an effective modality for the management of LUTS suggestive of bladder outlet obstruction, a considerable number of patients fail to achieve satisfactory relief of symptoms. Therefore, the burning question regarding TUMT is how to select patients who will respond favorably to heat therapy. The ideal patient for this modality has yet to be fully characterized. Controversial results have been reported

regarding whether or not prostate size, severity of symptoms, or baseline serum PSA levels can predict clinical outcome of microwave heat therapy, and this represents a source of disagreement among authors. It is very difficult to identify predictive baseline parameters for TUMT, since different devices have been used and studies suggest that a predictive factor for one particular device is not necessarily of value for other devices [81]. However, advanced patient age, small prostate volume, mild-to-moderate bladder outlet obstruction, and a low amount of energy delivered during treatment are considered to be independent baseline parameters predicting an unfavorable outcome [82].

Cost

The introduction of new technology in healthcare is sometimes charged as one of the major causes of escalating costs due to the purchase of the capital equipment and failure in terms of efficacy, morbidity, and durability. Different economic models evaluating the cost-effectiveness of minimal invasive therapies for BPH have been introduced [83, 84]. However, the cost-effectiveness of all techniques depends on the existence of long-term data, costs of complications or retreatment, and the different reimbursement systems in different countries. Therefore, it is difficult to draw solid conclusions that are applicable to every country.

When applying the different models, it seems that TUMT is cost saving and a reasonably cost-effective alternative to both TURP and medical therapy for treatment of moderate-to-severe BPH [83, 85]. Savings also depend on the number of men who seek treatment for BPO [86]. The initial fixed cost of TUMT compared to TURP is compensated by the large treatment capacity, which lowers the relative cost per patient. DiSantostefano evaluated the incremental cost-effectiveness of BPH treatment alternatives [87]. He used a Markov model over a 20-year time horizon and the payer's perspective to evaluate the cost-effectiveness of watchful waiting (WW), pharmaceuticals (alpha-blockers, 5-alpha-reductase inhibitors, combination therapy, TUMT, and TURP) in the management of BPH. It was found that alpha-blockers and TURP appear to be the most cost-effective alternatives, from a US payer perspective, for BPH patients with moderate and severe symptoms, respectively. TUMT was promising for patients with moderate symptoms and the oldest patients with severe symptoms, but for other patient groups other therapies were more cost-effective [87].

In general, performance of treatment on an outpatient basis represents a critical factor that reduces the direct

cost and renders TUMT economically advantageous compared to surgical treatments. However, this benefit may be balanced by the higher retreatment rate of TUMT.

Current position of TUMT

Data from the Urologic Diseases in America BPH project showed that BPH therapy trends are moving away from the gold standard operation of TURP and toward less invasive pharmacologic options and minimally invasive therapy in an outpatient setting [88]. In addition, the aging of the population has resulted in longer waiting lists and a growing demand for effective and cost-worthy alternatives. Into this frame, TUMT is one of the best studied minimally invasive therapies and high quality data are available. Based on these data, the European Association of Urology (EAU) Guidelines state that TUMT is considered as the most attractive interventional modality alternative to TURP, and should be reserved for patients who want to avoid surgery or do not respond favorably to medication [89]. According to the American Urological Association (AUA) Guidelines, TUMT is effective in partially relieving symptoms in BPH patients, but there is no evidence of superiority of one device over another [90]. The 6th International Consultation on New Developments in Prostate Cancer and Prostate Diseases concluded that TUMT has good clinical outcomes that seem durable and low morbidity, and it represents an option when instrumental treatment is indicated (except when an absolute indication for surgery exists) [91].

However, in spite of many well-conducted positive studies, the better understanding of thermotherapy and the sufficient clinical documentation, the clamor from the acceptance of TUMT in daily clinical practice is not pertinently loud. Plausible reasons include the fact that initial enthusiasm for most of the minimally invasive alternative treatments often fades away with time, and the development of new technologies for BPH treatment. In addition, there is a significant difference in acceptance of TUMT between Europe and the USA. A survey performed in 2001 during the EAU meeting showed that only 18.5% of 854 European participants had already had access to TUMT [92]. However, when asked what kind of equipment they would like to have access to among the alternative minimally invasive techniques, 40% preferred the holmium laser, 11% electrovaporization, 5% transurethral needle ablation (TUNA), 5% TUMT, 4% Gyrus, and 3% interstitial laser coagulation, while 61.5% of the respondents did not choose any of the proposed equipment. It was considered that these results reflected urologists' satisfaction with the devices to which they had access, different fields of interest or misbeliefs in the clinical potential of alternative treatments [92]. Recently, Yu *et al*. performed an important Medicare-based study and showed that the total rate of BPH procedures increased significantly after 2002 due to the marked increase of new minimally invasive surgical treatment procedures [93]. By 2005, these represented 57% of total BPH surgeries in the USA, while TURP represented only 39% (vs 81% in 1999). The most commonly performed minimally invasive surgical treatment in 2005 was TUMT (22.7% of all BPH procedures). Furthermore, reimbursement policy encourages outpatient management of urologic diseases. A review of the 2008 Medicare fee schedule physician reimbursement for TUMT indicates an approximate value of $2901.75 in the office site of service and $536.34 for a hospital-based procedure [94]. In addition, it has been reported that while in 1999, 83% of TUMTs were performed in the hospital outpatient setting, by 2005 almost all TUMTs (98.9%) were performed in clinician offices [93]. This high in-office reimbursement of TUMT relative to TURP, availability of TUMT devices, and patient preference may have driven the move to the office/outpatient setting where TUMT dominates, and this may explain the discrepancy between the use of TUMT in Europe and in the USA.

Conclusions

TUMT is established as a safe and effective minimally invasive alternative to treat symptomatic BPH, but it is not as effective as TURP. However, given the low morbidity of TUMT, a higher risk of retreatment may be a reasonable trade-off for patients with LUTS due to BPH. In addition, there are different approaches regarding the adoption of TUMT in clinical practice, depending on local conditions of reimbursement, an institution's financial support, and personal preferences. Into this frame, TUMT tailored to selective cases remains an attractive option.

CHAPTER 125
Transurethral Needle Ablation of the Prostate

Alexandre R. Zlotta & Cynthia Kuk

Division of Urology, Mount Sinai Hospital, Department of Surgical Oncology, Princess Margaret Hospital, University Health Network, University of Toronto, Toronto, Canada

Introduction

Surgical therapy, despite being considered the "gold standard" treatment for lower urinary tract symptoms (LUTS) secondary to benign prostatic hyperplasia (BPH) in the past, is now considered second-line therapy and is usually reserved for patients who have failed medical therapy or minimally invasive treatments, or patients with absolute indications for surgery. The number of minimally invasive surgical treatment procedures for BPH from 1999 through 2005 among elderly male Medicare beneficiaries increased 529%, and the transurethral resection of the prostate (TURP) rate decreased approximately 5% per year. By 2005, minimally invasive surgical treatment procedures accounted for 57% of total BPH surgeries, while transurethral prostate resection accounted for only 39% [1].

Transurethral needle ablation (TUNA) is an office-based minimally invasive therapy, first introduced in 1993 by the Ed Stewart-Vidamed Company. It relies on delivering energy via a radiofrequency (RF) generator, an optical transurethral device, and two needles that allow selective necrosis of tissue. The TUNA system delivers low-level RF energy through the two needles inserted into the prostate and thermally ablates a well-defined region of the enlarged prostate. Teflon shields were used from the very beginning of the TUNA technique to protect the urethra from heat damage. There has been a constant evolution in the equipment since initial reports.

The initial idea in the early 1990s came from the rationale that if RF is safe enough to selectively ablate aberrant heart bundles responsible for cardiac arrhythmias, it could be safe enough to ablate hypertrophic benign prostatic tissue. Interestingly, catheter ablation therapy for arrhythmias has also evolved over the past 20 years to become the first-line therapy, facilitated by technology that has allowed better anatomic and electrophysiologic correlations. A better understanding of RF ablation has led to safer and more effective treatments, and this has become a potent diagnostic and therapeutic tool in clinical cardiac electrophysiology [2].

TUNA has now been for many years an accepted therapy for the treatment of LUTS due to BPH. In October 1997, the Food and Drug Administration (FDA) approved the TUNA system for the treatment of BPH. The TUNA® system (Medtronic Inc, Minneapolis, MN, USA) and the TUNA Office System, an updated version of the original system, received 510K approval from FDA as a Class II device in February 2001. In November 2005, the FDA granted 510K clearance for the Prostiva™ RF Ablation System, stating that it is substantially equivalent to TUNA® Therapy (the previous name for this product), and this remains the only currently FDA-approved TUNA system in the USA.

In the UK, guidance on the safety and efficacy of interventional procedures is produced by the Interventional Procedures Program within the National Institute of Health and Clinical Excellence (NICE) [3]. In October 2003, NICE issued guidance on the use of

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

TUNA for the treatment of benign prostatic obstruction (BPO). According to the NICE guidance, the literature demonstrated that TUNA was a safe procedure with fewer postoperative complications (e.g., bleeding) than TURP and was efficacious in the short term. The guidance noted that the current evidence was adequate to support the use of TUNA in the treatment of BPO provided the normal arrangements are in place for consent, audit, and clinical governance. The long-term efficacy has yet to be established though [3].

The American Urological Association (AUA) guidelines [4] state that TUNA is effective in partially relieving the symptoms of BPH. For the relief of symptoms in the average patient, TUNA appears to be more effective than medical therapy but less effective than TURP. The ideal patient for this procedure is a man who has obstructive BPH, a prostate of 60 g or less, and predominantly lateral lobe enlargement.

In France, TUNA has been recommended by the Haute Autorite de Sante (HAS) since its report in 2006 [5].

Part of the difficulty in assessing clinical practice guidelines is the differences in methodology and rigor of development that can lead to varying recommendations (e.g. several recommendations of the European Association of Urology guidelines [6] differ from those of the AUA guidelines). Nevertheless, clinical practice guidelines provide a framework for discussion and should be used in the context of overall healthcare delivery.

The advantages of the TUNA procedure over the more invasive surgical resection are the ease of performance in an outpatient setting with minimal anesthesia and avoiding the major complications of the transurethral resection procedure. In addition to relief from the bothersome symptoms, preservation of a certain quality of life and sexuality are very important for patients as well.

This chapter will review the TUNA procedure, evolution in technique and equipment, clinical outcome, long-term efficacy, and side effect profile.

Principles of thermal ablation techniques

Many different minimally invasive thermal ablative techniques have been described for treating benign and malignant tumors. The principal mechanism of tissue necrosis is the same and does not depend on the frequency of the electromagnetic energy, i.e. whether radiowaves, microwaves or visible light, but the frequency determines the extent of the uptake and dissipation in the tissue. The heat generated (in Joules) is a product of the power applied (in Watts) and duration of application (minutes and seconds), and its diffusion is related to the impedance of the tissues treated. All thermal effects are influenced negatively by blood flow, as this removes heat before the tissue is completely ablated (the heat-sink effect); this effect protects blood vessels and prevents bleeding of large vessels, and is a reason for incomplete ablation, which may be an important concern in oncology, e.g. in renal tumor ablation. This is certainly less of a concern in BPH.

With TUNA, low-level RF energy (473 kHz) passes from two active electrode (needles) to the prostatic tissue, then to the ground pad in a monopolar fashion, and then back to the generator. RF energy allows greater control and more uniform temperature distribution than microwaves (300–3500 MHz). When the RF energy meets tissue resistance, it is converted into thermal energy via molecular agitation (direct heating). Heat is conducted further into the tissue via "cell-to-cell" conductive heating. The amount of heat energy produced and the subsequent thermal effect are determined by the amount of tissue contact (length of the needle) and power level (wattage). Temperatures above 50°C cause coagulative necrosis of tissues following a well-defined "time–temperature" toxicity curve [7–9].

TUNA (Prostiva RF System) achieves temperatures of greater than 100°C in selected areas of the prostate and core temperatures of around 115°C. The TUNA cartridge consists of a specialized cystoscope connected to a RF generator. Two flexible needles, which can be deployed at an acute angle of 40° to each other and at 90° to the catheter, emerge at the bullet-shaped catheter tip for an adjustable length of 12–22 mm that the urologist will adapt depending on the gland size and shape. The originality of TUNA as compared to other minimally invasive procedures lies in the Teflon shields that cover the base of the needles in order to protect the urethra from high temperatures. The rationale is to produce necrotic lesions inside the prostate parenchyma while trying to spare prostatic anatomy (both the urethra and prostate capsule) in order to minimize postoperative side effects. An optical path within the catheter allows the accurate positioning of the catheter within the prostate under direct vision, similarly to any cystoscopic procedure.

Evolution of techniques and equipment

The TUNA procedure (S Edwards, Vidamed Company, Palo Alto) was introduced in the early 1990s, followed in several countries by first investigations in animals and humans. In Israel, Goldwasser and Ramon demonstrated large necrotic lesions with TUNA of the canine prostate and in *ex vivo* human prostates [10, 11]. At the same time in Belgium, and for the first time in humans, Schulman *et al.* performed a pilot study in patients to evaluate TUNA feasibility, safety, and histopathologic assessment of thermal lesion size by: (1) monitoring ure-

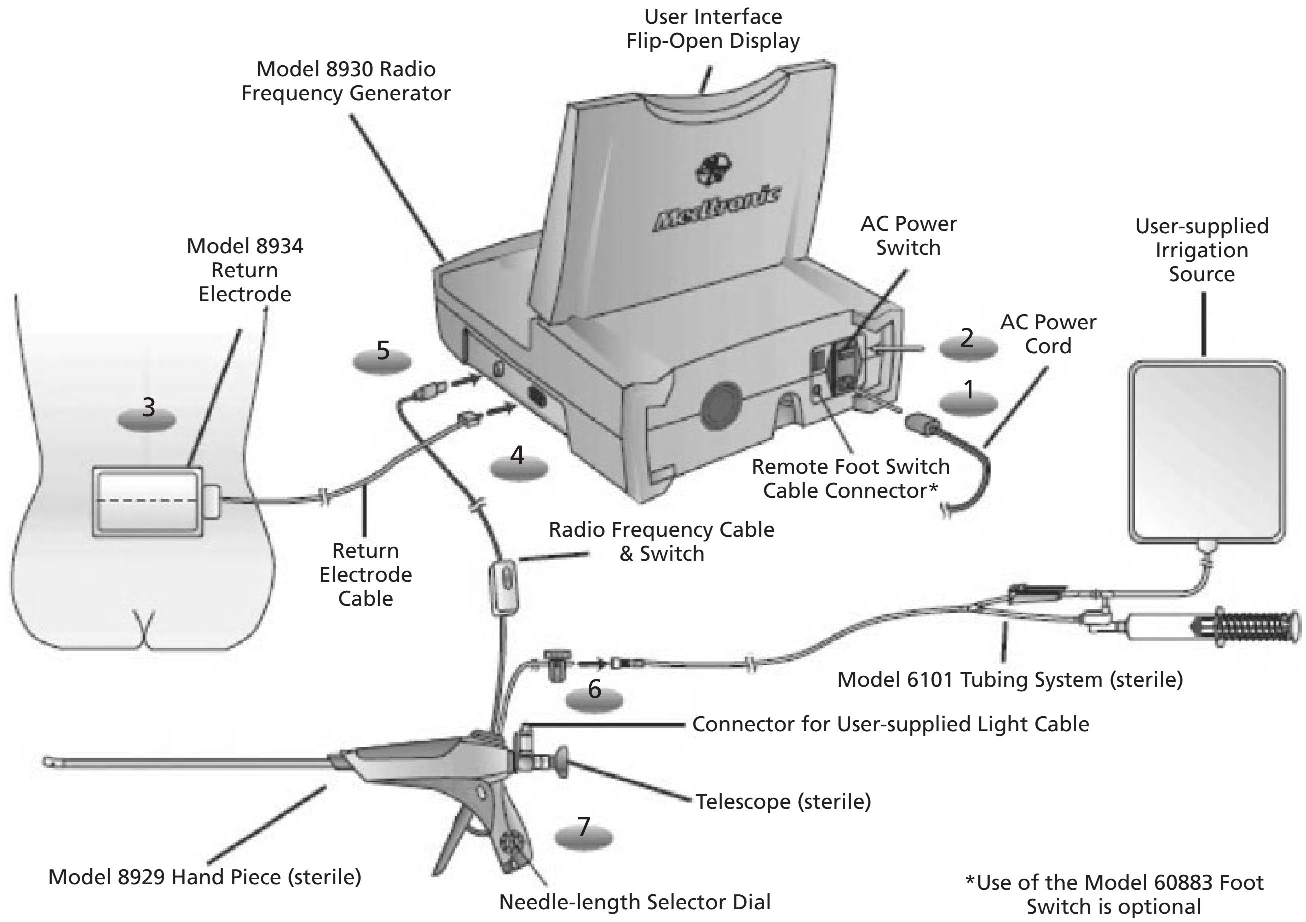

Figure 125.1 Current systems (courtesy of Medtronic).

thral and rectal temperatures; (2) assessing the ability to localize lesions; and (3) determining patient tolerance of the procedure without anesthesia [12]. Twenty patients were treated using TUNA prior to scheduled retropubic prostatectomy. The surgical prostatic specimens were recovered from 1 day to 1 month after TUNA, step-sectioned, and examined histologically. The TUNA procedure averaged 27 min (far longer than today), four lesions were produced per prostate, and 4–15 W of power were applied for 3 min. The proximal lesion temperature was about 40–50°C with central lesion temperatures of about 80–100°C. Urethral temperature averaged 37–42°C and rectal temperature remained unchanged. Macroscopic examination of the specimens demonstrated localized lesions averaging 12×7 mm. Microscopic examination showed lesions of extensive coagulative necrosis averaging 30×15 mm. Immunohistochemical staining showed destruction of all tissue components, including adrenoreceptors [12]. An infrared thermal gradient mapping and comparison of lesion sizes in a tissue model and in patients with BPH were also performed [7].

The early clinical experience and feasibility of TUNA (using the first-generation technology) under local anesthesia was published by Schulman and Zlotta [13]. Results were confirmed by several groups in the mid/late 1990s in Israel, Italy, South Africa, the UK, Canada, Australia, the USA, Sweden, Ireland, Israel, Norway, and Germany [14–26]. These initial reports showed that TUNA of the prostate appeared to be a simple, safe (very few side effects, especially on sexual function and urinary continence), and efficacious procedure for treatment of symptomatic BPH, given without general or spinal anesthesia and using only topical urethral anesthesia or local prostatic block. They also confirmed the extent of the lesions produced. However, the technique and equipment used clearly required improvements and it was hoped and anticipated that these would also translate into improved outcomes. In addition, most of these studies were non-randomized.

Figure 125.1 illustrates the evolution in technique and equipment since TUNA's early development phases. We first used TUNA in 1993, in purely ultrasound-guided models without optics. There has been a

constant evolution in the development of TUNA generators and catheters since the first generation was launched in 1993 (22–26G needles).

With the first models, direct visualization of the needles was not possible when deploying them into the prostatic tissue. Temperatures were read by thermosensors placed not at the tip of the needle but on the shields of the needles that were deployed, and thus at the periphery of the lesion in the making. They could not be measured at the tip of the needle, and therefore at the center of the lesion, because needles at that time were not hollow. The power delivered had to be adapted manually according to the impedance of the tissue. If the power delivered was too high, it caused rapid desiccation of the tissue around the active needles, increased the impedance, and thus prevented any further delivery of RF waves into the tissue. Using these first generator models, urologists at times had to find a precarious balance between the appropriate energy level required to continue to drive the development of the lesion and the rise in temperature. If the latter was too rapid because excessive energy had been delivered, it caused a sharp increase in impedance and led to charring of the tissue around the active needles, preventing further tissue ablation. To manually adapt the power, constant monitoring by the urologist of both needle placement and generator keyboards was necessary. The procedure was not completely reproducible and unavoidable variability occurred. Maximum temperatures had to be reached within about 1 min of treatment, and then maintained for at least an additional 3 or 4 min without variation in the impedance itself. This was sometimes difficult to achieve.

In 1997, the ProVu system introduced improved optics with an automatic shield of deployment. With this new catheter, needles and protecting shields could be viewed as they entered the prostatic lobes, a routine with cystoscopic procedure. Reusable handles with disposable cartridges were also introduced along with an 18.5F delivery system. In 2002, a new generation of TUNA catheters and generators, Precision Plus™, was developed. In contrast to the first-generation catheters, thermosensors could now be placed at the tip of the needle to give the maximum temperature at the core of the lesion (Figure 125.2). There was no longer a need to extrapolate the maximum temperature in the lesion itself from readings at the shield. This obviously both standardized and simplified the procedure. Lesion time was 25% faster (3 min) and larger needles (24G) were provided for more consistent heating in all types of tissue.

As we had done with the first TUNA system, we analyzed the extent of the thermal lesions induced by 2, 3, and 4 min of treatment using the new TUNA Precision Office system in 10 patients treated with TUNA immediately prior to retropubic prostatectomy for BPH. Histologic sections were stained with NADPH and H&E (Figure 125.3) to analyze thermal damage and necrosis on macroslides (Figure 125.4). All treatments were performed in the right lobe and the left prostatic lobe was left untreated and used as the control. Lesions created with 2 min of treatment (up to 14 × 10 mm) were smaller than those created with 3 and 4 min of treatment [27].

In 2006, the latest technology, the Prostiva RF, was introduced. This generator is fully automated and can deliver energy much more rapidly, creating a lesion in about 2 min 20 s (much faster than the Precision Plus), with a target temperature of 115°C. Integrated disposable hand pieces are another feature of this improved system. Needles can be deployed at a depth of 12, 14, 18, 20, and 22 mm into the prostatic parenchyma as required (Figure 125.5).

The new generators are much lighter (7 lb) and more compact than the originals (Figure 125.6). The set-up is undoubtedly easier and a new user interface with touchscreen controls adds to the user-friendliness of the system. On the hand piece, 6-Hz monitors control urethral and prostatic temperatures, whereas a 5-kHz monitor controls RF power. The 50-MHz controls measure impedance and power. Computerized graphics allow the urologist to view treatment in realtime (Figure 125.7). The rod–lens telescope is compatible with all medical-grade video camera systems and light sources, and can be used with direct vision. The telescope is a rigid optic telescope with a 0°/15° viewing angle and is designed for reuse by autoclave sterilization. The hand piece is single use.

Treatment procedure

The TUNA procedure is performed with the patient in the lithotomy position. The device is inserted via the urethra down to the prostatic area, under fiberoptic vision control, as in any simple cystoscopic procedure. The catheter shaft is rotated in order that the needles face the prostatic lobe to be treated. The catheter is placed in contact with the prostatic urethra, and the needles and shields are deployed. Of note, the operator has to imprint a slight pressure on the lobe before deploying the needles to ensure their penetration without the tip of the catheter being pushed away from the lobe by the resistance on the needles. The needles are deployed at the 10 and 8 o'clock positions in the right lobe, and at the 2 and 4 o'clock positions in the left lobe. The length of the needles and extent of shield deployment are determined by preoperatively by measuring the transverse section of the prostate using transrectal ultrasound. In the Prostiva RF generator, a table indicates optimal needle length according to the prostate's transverse diameter (Figure 125.8). Needles should not be deployed more than 6 mm

less than half the diameter of the prostate to avoid thermal injury beyond the prostatic capsule, including damage to the neurovascular bundles, although arguably for the lateral lobes of the prostate, this may not be important. Both lateral lobes are treated in two to five planes (depending on the size of the prostate), starting 1 cm from the bladder neck to 1 cm proximal to the verumontanum (Table 125.1). The number of lesions to be created for different prostate sizes and bladder neck–verumontanum lengths is presented in Table 125.2. Treatment recommendations for different median lobe dimensions are given in Table 125.3.

Prostiva generators are equipped with computer-assisted software that automatically adapts the power delivered into the tissue according to the measured impedance. The system can reach temperatures above 110°C and maintain this for the 2.20-min coagulative ablation lesion time.

Anesthesia requirement

There is a wide variation in the anesthetic requirement for TUNA therapy between different institutions and urologists. With experience, the procedure can be conducted under local anesthesia only, which may include intraurethral lidocaine gel, intravesical liquid lidocaine, transrectal periprostatic block, or a combination of these. Supplemental oral or parenteral sedation/narcotics may be used, if required. This was given at the beginning of the TUNA experience.

Regarding local anesthesia, the bladder is first emptied using a catheter, then 40 mL of cold (4°C) injectable liquid lidocaine is injected into the bladder through the same catheter (Table 125.4). Lidocaine gel 20 mL is then instilled into the urethra and the penis clamped for 10–20 min before the procedure. For a periprostatic block, 10 mL of xylocaine 1% is injected under transrectal ultrasonography into the lateral base of the prostate, exactly as is usually does for transrectal prostate biopsies. Nowadays, most procedures are indeed performed very similarly to prostate biopsies. Numerous randomized prospective trials have demonstrated the usefulness of transrectal injection of various anesthetics [28–30]. Issa *et al*. performed a prospective multicenter study of transperineal (rather than transrectal) prostatic block in TUNA in 39 men with symptomatic BPH [31].

In our personal experience, TUNA can be easily performed under local anesthesia with transrectal ultrasound-guided injections starting from the seminal vesicles down to the prostatic apex. The prostate is lifted upwards and a plane below the prostate is very clearly visible as a large hypoechoic zone that penetrates the

<3 cm wide	1	10, 12, 2 o'clock
3 cm wide	2 or more	10, 12, 2 o'clock
3 cm long	1	12 o'clock
>3 cm wide	2	6, 12 o'clock

Table 125.4 Suggested local anesthesia (courtesy of Medtronic).

Step 1: 60 min preprocedure
Oral analgesic 10.0 mg oxycodone with paracetamol/ acetaminophen (Percocet)
Oral sedative 10.0 mg diazepam
NSAIDs 50.0 mg rofecoxib (Vioxx)
Antibiotics
Anticholinergics 4.0 mg tolterodine tartrate (Detrol LA)
Step 2: 20 min preprocedure
Place patient in a semi-Fowler's position
Empty bladder with the catheter
Instill 40 of –60 mL cold (4°C) liquid lidocaine 2% injectable vial into the bladder via the catheter
Slowly pull catheter out while continuing to instill the last 10 mL of lidocaine into the urethra
Instill 20 mL of lidocaine gel, clamp the penis

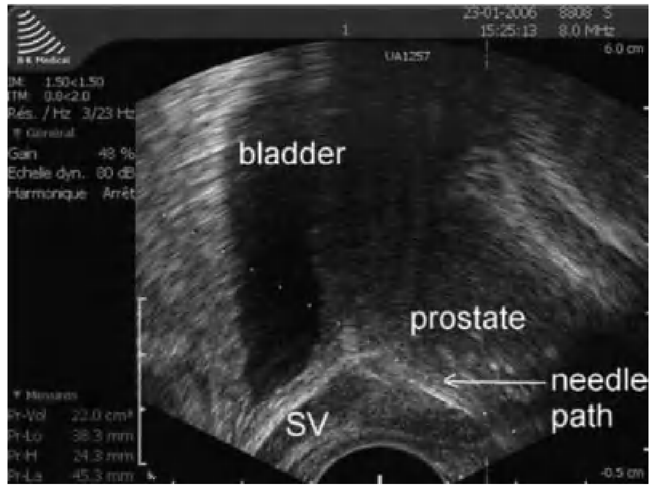

Figure 125.9 Local anesthesia: a needle is introduced through the transurethral ultrasound (TRUS) probe in the plane between the rectum and the prostate up to the seminal vesicles (SV). Anesthetic is injected while withdrawing the needle from the base to the apex of the prostate (with kind permission from Springer Science + Business Media: *World J Urol*, How do I treat and follow my TUNA patients, 24:4, 2006, Sas Barmoshe).

tissue at that level (Mount Everest sign). Local anesthesia (5–7 mL) is given on each side of the prostate (Figure 125.9). The prostatic block has dramatically improved the tolerance of the TUNA procedure. Leocadio *et al.* successfully treated 56 consecutive patients with office-based TUNA using oral rofecoxib (50 mg) and ciprofloxacin (250 mg) before administering 25 mg of hydroxyzine and 50–100 mg of meperidine intramuscularly [32].

Mechanism of action

Histologic examination shows that radiofrequency ablation of the prostate leads to localized, spheroidal, reproducible necrotic lesions up to 4 mm from the needles; neurohistochemical analysis shows severe thermal damage to intraprostatic nerve fibers that extend beyond the area of tissue necrosis, and it has been postulated that this may contribute to clinical improvement.

We investigated the mechanism of action of TUNA by analyzing 10 open prostatectomy specimens (BPH) recovered 1-46 days after TUNA. These were stained with H&E and an immunohistochemical technique that used antibodies against S100 proteins and nonspecific enolase as specific nerve markers, and against antiprostate-specific antigen (anti-PSA) and antidesmin for glandular and muscle cells, respectively. We used five BPH specimens as controls. Nerve fibers in the control specimens and untreated prostatic areas predominated in the urethral submucosal layer and stroma surrounding the epithelial nodules, with a quasi absence of nerve endings in the prostatic stroma. The sparsity of nerve endings in the prostate adenoma possibly explains the excellent tolerance of TUNA as an anesthesia-free, minimally invasive treatment, provided the urethral and capsular nerve endings are taken care of with local anesthetics. No staining of any axon or nerve cell was observed in any specimen treated by TUNA, and there was a sharp and clear delineation between treated and untreated areas. Severe thermal damage to intraprostatic nerve fibers caused by TUNA was demonstrated. This study suggested that long-term denervation of alpha-receptors and/or sensory nerves could explain the clinical effects of TUNA of the prostate.

We have also shown using magnetic resonance imaging (MRI) that the first-generation TUNA systems induced large coagulative necrotic lesions of a size in line with that anticipated size from the needle deployment [8].

Huidobro *et al*. analyzed dynamic, gadolinium-enhanced MRIs to characterize the ablative properties of the Prostiva RF device in 10 men with LUTS due to BPH [33]. Gadolinium-enhanced MRI sequences were obtained prior to and 1 week post treatment. New gadolinium defects were seen in all patients following

Prostiva treatments. All lesions coalesced within the prostate. No defects were seen beyond the prostate and the urethra was spared in all patients. The mean volume of necrosis was 7.56 mL, representing a mean of 11.28% of total prostate volume. The standard Prostiva RF protocol produced lesions that coalesced to create larger lesions in the bladder neck and lateral lobes. , The ablative lesions were comparable to those produced with the TUNA Precision Plus device, but were achieved with a shorter burn time [33].

It is clear that the amount of tissue "debulked" is relatively small and that TUNA efficacy cannot scientifically be explained by its mechanical action on the bladder outlet obstruction alone. There is very likely to be a "dynamic" mechanism of action as well, possibly similar to that observed using medical therapy (alpha-blockers). Fine-tuning of our understanding of the mechanisms of action may require additional studies.

Indications

Patients considered for RF ablation meet the following criteria:

- Moderate to severe BPH symptoms without clear indication for surgery;
- Dissatisfied with medication results or side effects, concerned about inconvenience of lifelong medical therapy;
- Concerned about side effects associated with surgery or not appropriate candidates for surgery.

RF ablation is contraindicated in patients with active urinary tract infection; neurogenic, decompensated, or atonic bladder, urethral strictures that prevent insertion of the cartridge sheath; malleable penile implants; bleeding disorders or on anticoagulation medication unless antiplatelet medication has been discontinued for at least 10 days; and presence of any prosthetic device in the region that may interfere with the procedure. In patients with a cardiac pacemaker or implantable defibrillator, there is a potential risk due to the interference between RF frequency and the pacemaker, but we have performed the procedure safely in such patients. The advice/presence of an anesthetist is suggested, as well as the availability of a magnet in the room.

Prostate volume

Prostate lobes of varying sizes and shapes can be treated, including asymmetrical prostates and median lobe (except those that grow into the bladder and collapses across the bladder). Studies analyzing the effect of TUNA on patients with median lobe enlargement report improvements similar to those in the general population with symptomatic BPH [34, 35]. However, prostate glands less than 34 mm or greater than 80 mm in transverse diameter are usually not recommended for treatment. Our personal opinion is that the most suitable prostate sizes are between 20 and 50 cm^3; however, this may be debatable (Table 125.5) [8, 16, 24, 26, 36–43].

Clinical efficacy

Meta-analyses

The short- and long-term effectiveness of TUNA of the prostate for clinical BPH has been published in two systematic review and meta-analyses [44, 45].

Boyle *et al.* extracted data from two randomized trials, two non-randomized observational protocols, and 10 single-arm studies conducted on TUNA, according to a determined protocol [45]. The meta-analysis was based on the change in the mean score at the end of study from that at baseline. The estimation of the effects from the meta-analysis used a multilevel model including random effects for the studies. TUNA was found to halve the mean International Prostatic Symptom Score (IPSS) at 1 year after treatment and, although there was a slight tendency for the IPSS to increase in all arms from year 1 to year 5, this decrease was maintained at 5 years. The maximum urinary flow rate (Qmax) also increased by approximately 70% from baseline to 1 year. Although there was a tendency for Qmax to decline slightly over time, the mean Qmax 5 years after treatment was about 50% over baseline. This meta-analysis concluded that TUNA was an effective and minimally invasive treatment for men with clinical BPH, even when symptoms were severe. It appeared to be an alternative to surgery and an attractive option for men who do not wish to undergo long-term medical therapy, are poor candi-

dates for surgery or are concerned about the side effects of TURP.

A second and larger meta-analysis was reported in Spain by Bouza *et al.* [44]. The authors postulated before embarking on their study that its impact on BPH and role among other currently available therapeutic options were unclear. In order to ascertain the efficacy and safety of TUNA in the treatment of BPH they performed a systematic review of the literature up to January 2005 and a meta-analysis of clinical studies assessing TUNA in symptomatic BPH. Studies of 10 or more patients that contained relevant primary clinical data were critically appraised. Estimates of effect were calculated according to the random-effects model. Two independent reviewers carried out the study selection and data extraction. A third reviewer checked the extracted data and the team resolved any discrepancies. Thirty-five studies (nine comparative, 26 noncomparative) were included that assessed TUNA versus TURP and other minimally invasive techniques. No study comparing the efficacy and safety of TUNA with medical treatment was found in the literature to date.

Although evidence was limited by methodologic issues, the analysis of relevant outcomes indicated that while TUNA significantly improved BPH parameters with respect to baseline, it did not reach the same level of efficacy as TURP in respect to all subjective and objective variables. Further, its efficacy declined in the long term with a rate of secondary treatment significantly higher than for TURP (OR 7.44, 95% CI 2.47–22.43). Conversely, TUNA seemed to be a relatively safe technique and showed a lower rate of complications than TURP (OR 0.14, 95% CI 0.05–0.14), with differences being particularly noteworthy in terms of postoperative bleeding and sexual disorders. Likewise, TUNA had fewer anesthetic requirements and generated a shorter hospital stay than TURP [weighted mean difference (WMD) −1.9 days, 95% CI −2.75 to −1.05]. Available evidence suggested that TUNA is a relatively effective and safe technique in selected patients with symptomatic BPH. The review indicated that there were insufficient data to define with any degree of accuracy the role of TUNA *vis-à-vis* other minimally invasive therapies.

TUNA leads to a significant improvement in both subjective and objective variables over preintervention values (Table 125.6) [15, 16, 24, 26, 36–40, 42, 43, 45–47]. TUNA reduces the symptom index and quality-of-life score by 50–60% with respect to pretreatment values, an improvement that is maintained across follow-up, though a progressively downward trend is evident after 3 years. With respect to the objective parameters, TUNA leads to improvements which, though significant, amount to an increase of around 30–35% over baseline values. Its effect, albeit to a minor degree, is also demonstrated in terms of improvement in urodynamic parameters [26]. Some authors have suggested the effect of TUNA on objective variables is weaker in the case of prostates larger than 50 g. Others, however, do not observe that size exerts a significant influence on patients' response and suggest that this should not be an exclusion criterion for the use of the system.

In the meta-analysis by Bouza *et al.*, 15 studies [13, 18, 25, 35, 37–39, 42, 48–55] provided data on the need for new interventions following TUNA and, though their individual results varied widely, combined analysis indicated that 237 of 1036 patients treated with TUNA required new treatments, amounting to an overall

retreatment rate of 19.07% (95% CI 18.7–39.7) [44]. These new treatments mainly consisted of surgical measures, namely TURP (150 cases), unspecified surgery (22), second TUNA (7), prostatectomy (6), and transurethral incision of the prostate (1). A total of 41 patients received drug therapy. In 10 cases, the treatment employed was not specified.

Comparative studies

Transurethral needle ablation versus transurethral resection of the prostate

The general and methodologic characteristics of studies comparing TUNA with TURP are shown in Table 125.7 [15, 36, 48, 56–61]. In terms of design, four were non-randomized and five were randomized studies. The total number of patients included in randomized studies was 336 (167 treated with TUNA, 169 with TURP).

Both techniques provide significant improvements in BPH parameters and, initially, the efficacy of TUNA would seem to be equivalent to that of TURP. However, at 12 months, subjective parameters and objective functional measures are both statistically better with TURP.

The combined results of the meta-analysis of Bouza *et al*. indicated that TUNA had a retreatment rate significantly higher than that of TURP: 10% (21 of 206) of patients treated with TUNA versus a mere 1% (3 of 282) of TURP patients [44]. Rosario *et al.* demonstrated a high retreatment rate in their study as well; however, it should be stressed that their study was performed using older versions of catheters and generators [62].

The effects of treatment on sexual function were analyzed in three studies [15, 56, 57] that used different scales. In one randomized clinical trial, 53% of the TURP versus only 13% of the TUNA cohort reported diminution in the volume ejaculated ($P < .001$) [15]. Cimentepe *et al.* observed that 100% of patients treated with TUNA reported no change in sexual function, whereas 61% of patients treated with TURP reported a deterioration [57]. Arai *et al.*, in a non-randomized study, observed a mild–moderate deterioration in erectile function in 26.5% of patients treated with TURP and 20% of patients treated with TUNA, without there being any significant change in the pre- and post-treatment indices of erectile function or libido in either group [56]. In 48.6% and 24% ($P < .001$) of TURP and TUNA patients, respectively, there was loss of ejaculation capacity or an appreciable diminution in the volume ejaculated. There was no mortality associated with either of these procedures, but a total of 67 and 417 adverse effects were reported for the TUNA and TURP groups, respectively. Adverse effects on sexual function were less frequent in the TUNA group. Treatment with TUNA resulted in a significantly lower number of complications than TURP (OR 0.14, 95% CI 0.05–0.41). Overall, TUNA entailed an absolute risk reduction of complications of 19.4% (95% CI 17–22%), with an estimated number needed to treat (NNT) of 5 (95% CI 5–6) to prevent a poor outcome.

Transurethral needle ablation versus other modalities

Only four studies have included comparison of TUNA with other minimally invasive techniques, such as: transurethral microwave thermotherapy (TUMT), water-induced thermotherapy (WIT), interstitial laser coagulation (ILC), transurethral electrovaporization (TUVP), visual laser ablation (VLAP), and transrectal high-intensity focused ultrasound (HIFU).

In a comparison of TUNA versus TUMT, at assessment at 3 months, TUNA-related improvements were significantly superior to those of TUMT in terms of symptom index, quality-of-life score, Qmax and postvoid residual volume (PVR); in addition, there was a trend, albeit nonsignificant, towards a lower number of erectile dysfunctions [63].

Likewise, TUNA seemed to have a significantly better effect than WIT on the objective variables analyzed in the study by Minardi *et al.* [61]. The results *vis-à-vis* ILC proved more difficult to analyze, as each techniques seemed somewhat more effective than the other, depending on the point in time at which they were evaluated. However, adverse effects tended to be more frequent in the group treated with ILC, particularly irritative symptoms, postoperative hematuria, and reduction in seminal volume.

Analysis of the studies comparing TUNA with TVP [59–61] indicated that TVP achieved improvements significantly superior to TUNA in both subjective and objective variables, but this was accompanied by a higher incidence of adverse effects.

Schatzl *et al.*'s results based on 30 patients indicated that, while both VLAP and TUNA led to similar improvements in symptom index, but VLAP had a significantly superior effect on objective variables [59, 60]. Furthermore, there seemed to be fewer adverse effects with VLAP.

Notable differences between TUNA and HIFU were not in evidence in the analysis of the 35 subjects in whom these techniques were compared [59, 60].

Long-term follow-up

Hill *et al.* reported on results of a prospective, randomized, multicenter clinical trial of TUNA versus TURP for the treatment of symptomatic BPH with 5-year follow-up (Table 125.8) [36]. A total of 121 men aged 50 years or older with LUTS secondary to BPH of minimum duration of 3 months were enrolled at seven medical

centers across the USA. Improvement from baseline for TUNA and TURP retained statistical significance at each interval for IPSS, quality of life, and Qmax. PVR was statistically significant at all time points for TURP and at year 5 for TUNA. The TURP group reported 41% retrograde ejaculation, while the TUNA group reported none. The incidence of erectile dysfunction, incontinence, and stricture formation was also greater in TURP than in TUNA cases, with significantly fewer adverse events for TUNA than for TURP.

Zlotta *et al.* reported on the 5-year follow-up of 188 consecutive patients with symptomatic BPH treated with TUNA in three different centers in Belgium, Greece, and Norway [37]. All patients were treated using the TUNA II or TUNA III catheters under local anesthesia only, without general or spinal anesthesia. Baseline and 5-year follow-up evaluation included Qmax, IPSS, and PVR. The number of patients requiring additional medical or surgical treatment was recorded. At a mean follow-up of 63 months, mean Qmax increased from 8.6 mL/s to 12.1 mL/s ($P < .01$, t-test), and IPSS and PVR decreased from 20.9 and 179 mL to 8.7 and 122 mL, respectively (both $P < .001$, t-test). The percentage of patients who improved by at least 50% on Qmax or IPSS was 24% and 78%, respectively. Mean prostate volume and PSA levels did not change significantly (53.9 mL vs 53.8 mL and 3.3 vs 3.6 ng/mL, respectively, at 5 years). Two patients died of unrelated comorbidities and 10 were lost to follow-up. Medical treatment was given to 12 patients (6.4%), a second TUNA was performed in seven patients (3.7%), and surgery was indicated in 22 of 186 (11.1%). Overall, 41 of 176 patients (188 at the start, two deaths, and 10 lost to follow-up) (23.3%) required additional treatment at 5-year follow-up. These authors concluded that TUNA provides good long-term clinical improvement at 5-year follow-up. More than 75% of the patients did not need additional treatment for BPH in the long run.

A recent European Association of Urology Real-Life Data Registry analysis of TUNA in over 500 men with LUTS/BPH aimed to provide information from reallife practice on long-term clinical outcome and economics of TUNA treatment for LUTS/BPH with the new Precision Plus and Prostiva RF systems [46]. The registry was set up by the EAU Clinical Research Office in November 2003 to collect follow-up data on 500 treated patients with a minimum of 5 years of follow-up. Enrolment was completed in July 2007. By early September 2009, 526 patients (mean age 66 years) had undergone TUNA at 20 centers in nine European countries. Mean prostate size at baseline was 43 g. Before enrolment, 13% of patients had been in acute urinary retention (AUR), 64% had received pharmacologic treatment (58% α-adrenoceptor antagonists), and 2.7% had undergone minimally invasive therapy. The mean procedure time was 31 min; 99% of patients were satisfied or very satisfied with the comfort during the procedure. Mean follow-up was 21.8 months, with 144 patients discontinuing mainly due to study completion (n = 20) or therapy failure [n = 91 (17%), including 53 patients requiring pharmacologic LUTS/BPH therapy and 30 requiring TURP]. Six-month, 1-year, 2-year, and 3-year follow-up data were available for 386, 308, 210, and 110 patients, respectively. In the 308 patients with follow-up data for at least 1 year, the mean follow-up was 26.8 months and the results for these patients are presented in Table 125.9. Eight-six complications [mainly AUR (41), gross hematuria (9), voiding symptoms (5) and infection (4)] occurred in 68 patients (22%); most complications [70 (81%)] resolved at analysis. AUR had resolved in 34 patients (83%) and required hospitalization in four patients. Retreatment rates, improvements in Qmax and symptom scores were very much in line with, if not slightly better than, with those previously published for the 5-year follow-up of 188

Table 125.10 Noncomparative studies of the safety of transurethral needle ablation (TUNA) (from Bouza *et al.* [44]; BioMed Central Ltd.).

Adverse effect	Number of events	Percentage of total patients
Hematuria:		
Mild	337	28
Moderate	85	7
Transitory unspecified severity	25	2
Severe	16	1
Transitory urinary retention	279	23
Dysuria	167	14
Irritative symptoms	117	10
Urinary tract infection	43	4
Pain during procedure:		
Moderate	11	0.9
Intense	4	0.3
Postoperative perineal pain	13	1
Epidydimo-orchitis	11	0.9
Mild–moderate burning sensation	10	0.8
High fever	8	0.7
Treatment halted due to intolerance to procedure	6	0.5
Urethral stenosis	6	0.5
Erectile dysfunction	4	0.3
Hemospermia	4	0.3
Retrograde ejaculation	3	0.2%
Loss of ejaculation	1	0.08
Prostatism	2	0.2
Complex bladder dysfunction	1	0.08
Damage to the mucosa	1	0.08
Deep vein thrombosis	1	0.8

patients treated with TUNA in three different European centers [37].

Transurethral needle ablation for patients in acute urinary retention

TUNA is an attractive treatment option in those patients who are a poor surgical risk. Zlotta *et al.* have shown TUNA to be a highly effective treatment for relieving AUR due to benign prostatic enlargement (BPE), with almost 80% of patients able to resume voiding spontaneously 2–27 days post-TUNA [55]. Similarly, Harewood *et al.* studied 10 patients with urinary retention. After the procedure, nine patients were able to void at a median time of 3 days [18].

Table 125.11 Catheterization post transurethral needle ablation (courtesy of Medtronic).

Study	Number of patients (%)	Mean catheterization time
Bruskewitz *et al.* [15]	26 (40)	24–48 h
Roehrborn *et al.* [24]	53 (40.8)	3.1 days
Kahn *et al.* [38]	45 (100)	1–5 days
Murai *et al.* [39]	93 (100)	24 h
	30 (32.2)	7 days
	1 (1)	>7 days
Minardi *et al.* [40]	24 (100)	2 weeks
Campo *et al.* [16]	16 (13)	48 h
Steele and Sleep [26]	8 (17)	1–9 days
Fujimoto *et al.* [42]	41 (100)	Up to 2 days
Sullivan *et al.* [43]	3 (30)	Within 3 days

Adverse effects

The description of adverse effects after TUNA is somewhat heterogeneous. Table 125.10 lists the adverse effects identified in the individual studies [44]. The most frequent adverse effect was hematuria, which in most cases took the form of mild bleeding. Retention occurred in 23% of patients but was usually transient, lasting only a couple of days. Dysuria, of lesser or greater intensity, irritative symptoms, which were usually transitory but were not clearly described, and urinary tract infections were other common adverse effects. Extremely few adverse effects with regard to sexual function have been described. Roehrborn *et al.* reported that 22% of patients analyzed reported pain and discomfort [24], and Daehlin *et al.* observed that 42% of their patients presented with moderate and 4% with major malaise [50].

Catheterization requirements post transurethral needle ablation

Studies reporting catheterization time post TUNA are summarized in Table 125.11 [15, 16, 24, 26, 38–40, 42, 43]. Most report catheterization times of less than 1 week.

Cost

The 24-month total procedural cost including expenditures for initial treatment, follow-up care, adverse events, and procedural retreatment after TUNA has been estimated at $6179 [9]. An analysis of 2008 Medicare physician reimbursement for TUNA shows approximate values of $582.43 and $2891.72 for the facility and

nonfacility settings, respectively. In practice, however, the procedure is generally performed in the office site of service by most physicians.

Transurethral needle ablation versus other instrumental therapies

The cost-effectiveness of TUNA was demonstrated in a 2001 study by Naslund *et al.* comparing TUNA, TURP, and TUMT [35]. The cost of each procedure was estimated from Medicare reimbursement for 2001 (Table 125.12) and the improvements in IPSS and Qmax at 4 years were used as the effectiveness outcomes. The cost-effectiveness of the different treatment options was calculated in dollars per unit IPSS improvement and dollars per mL/s improvement in Qmax. The study concluded that TUNA is the most cost-effective of the three options in improving symptoms of BPH (IPSS), and TUNA is more cost-effective than TUMT but less cost-effective than TURP in improving Qmax (Table 125.13). Another study by Rosario *et al*. suggests that the high retreatment rate associated with TUNA renders it relatively expensive when viewed as a long-term alternative to TURP for the management of LUTS associated with BPH [62]. They estimated that the additional cost during a 10-year follow-up was $1377. It should be noted that although this may be the case, TUNA was performed using older versions of catheters and generators. However, several features of TUNA make it an attractive treatment option from an economic point of view: Unlike TURP, TUNA can be conducted on an outpatient basis, reducing the cost of hospitalization. Hospital costs are further reduced due to low morbidity, lack of need for bladder irrigation, and low incidence of complications associated with TUNA. The fact that TUNA can be performed under local anesthesia translates into further (considerable) cost savings. The better safety profile of TUNA compared with TURP is of further value to patients, particularly the lack of sexual side effects following treatment with TUNA.

Patients treated with TUNA are able to return to their normal activities (including work) much quicker after the procedure than patients treated with TURP. A study by Sullivan *et al.* indicated that patients can be back to full activity within 72 h of TUNA [43].

Table 125.12 Comparative costs of transurethral needle ablation (TUNA), transurethral microwave thermotherapy (TUMT), and transurethral resection of the prostate (TURP) (courtesy of Medtronic).

Therapy	Cost of procedure (US$)
TUNA	2455
TUMT	2768
TURP	4500

Table 125.13 Comparative cost-effectiveness of transurethral needle ablation (TUNA), transurethral microwave thermotherapy (TUMT), and transurethral resection of the prostate (TURP) (the most cost-effective option is highlighted) (courtesy of Medtronic).

	Cost-effectiveness measure	
Therapy	Cost per unit IPSS improvement (US$)	Cost per mL/s Qmax improvement ($US)
TUNA	**49.10**	49.10
TUMT	55.34	79.12
TURP	64.30	**44.50**

Transurethral needle ablation versus medical management

In recent years, combination medical therapy has been introduced as a treatment option for BPH patients. The Medical Therapy of Prostate Symptoms (MTOPS) trial illustrated the benefits of combination medical management using an alpha-blocker and a 5α-reductase inhibitor in some men with BPH.

The results of this model suggest that the TUNA procedure compares favorably with combination therapy on a cost basis. From the payer's perspective, the break-even point between TUNA and combination medical management occurs after approximately 2 years 7 months. Monotherapy with tamsulosin remains less costly than TUNA for 5 years in this model. Monotherapy with finasteride is roughly equivalent in cost to the TUNA procedure over a treatment period of 5 years. When the cost of the mixed scenario medication model is compared with the cost of TUNA, the break-even point from the payer's perspective occurs after approximately 4 years of treatment (Figure 125.10) [63].

Conclusions

There is little doubt and argument about the fact that TUNA has gained its place in the urologist armamentarium for BPH. All major guidelines in the management of LUTS in patients with benign prostatic enlargement include TUNA of the prostate as a valuable treatment option in symptomatic patients with a low-to-moderate degree of bladder outlet obstruction, patients at high risk for surgery, and patients who wish to avoid surgery or regional/general anesthesia.

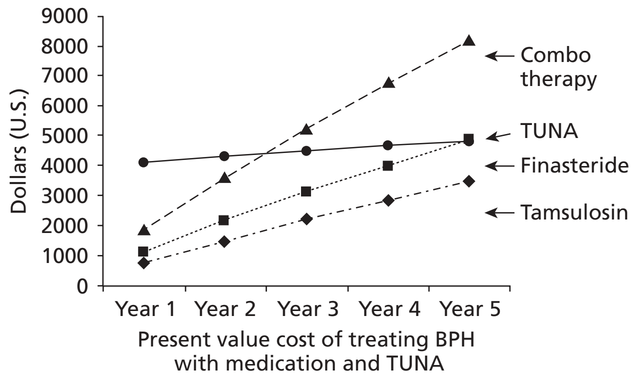

Figure 125.10 Present value cost of treating benign prostatic hyperplasia with medication and with transurethral needle ablation (TUNA) (reprinted from Naslund *et al*. [63], with permission from Elsevier).

The constant evolution in technique and equipment has made the procedure more rapid and more urologist and patient friendly. TUNA is usually performed in an office and under local anesthesia only.

Currently available evidence demonstrates a clinically relevant improvement of subjective (LUTS, quality of life) and objective parameters (Qmax). Impact on voiding dynamics, including detrusor pressure at maximum flow, as well as on prostate volume, remains marginal though, and a scientifically sound and unequivocal explanation for the TUNA mechanism of action remains to be elucidated. A likely permanent denervation from the extensive tissue necrosis is a possible explanation for TUNA efficacy.

TUNA bridges the gap between medical management and surgery. So far, most randomized studies have compared TUNA with TURP, but the indications and ideal candidates for these two procedures only partially overlap. As the indications for surgery and number of surgical procedures for BPH are rapidly decreasing, it seems inappropriate to try to place TUNA as an alternative for patients with clear indications for surgery. The large majority of patients with symptomatic BPH do not have clear indications for surgery, but are rather simply eager to see their symptoms resolved and their quality of life improved, without taking any medication (or without the burden of daily pills). An interesting future study would be to compare TUNA with medical therapy both in terms of outcome and cost-effectiveness.

Longer follow-up is still required to assess the very long-term efficacy of TUNA, but most data with 5 year follow-up, including a recent large-scale European study on 500 patients, suggest that outcomes are maintained long term, with at least 75% of patients not requiring additional therapies, although isolated reports have been less optimistic [46].

CHAPTER 126

Prostate Laser Vaporization Using the 980-nm Laser System

James C. Ulchaker

Glickman Urological and Kidney Institute, Cleveland Clinic Foundation, Cleveland, OH, USA

Introduction

For numerous decades, transurethral resection of the prostate (TURP) has been considered as the gold standard treatment for benign prostatic hyperplasia (BPH). Although TURP significantly improves lower urinary tract symptoms (LUTS), complications associated with this procedure, such as TURP syndrome and operative bleeding requiring blood transfusion, are still reported in up to 20% of operative cases [1, 2]. Consequently, alternative minimally invasive modalities have been developed. The 980-nm diode laser is one of these new treatment options. This laser wavelength is absorbed by both water and hemoglobin, thus combining high vaporization capacities and excellent coagulation properties [3]. This fact has been confirmed in more than one *ex vivo* porcine kidney model [4, 5]. Early results with the 980-nm wavelength *in vivo* are under investigation.

Herein, we describe the 980-nm laser: its unique wavelength characteristics, procedural techniques, results, limitations and complications, and potential future directions of this exciting new technology.

First, from a physical standpoint, the diode laser emits a wavelength of 980 nm, which is effectively absorbed by both water and hemoglobin. This is significantly different from the 532-nm wavelength, which is absorbed extremely well by hemoglobin, but poorly by water. It also differs from the 2100-nm laser in which the energy is highly absorbed by water, but insignificantly by hemoglobin. Thus, at 980 nm, prostatic tissue, which is constituted by significant amounts of both water and hemoglobin, can be effectively vaporized. Also, scar tissue and previously radiated prostate tissue, both of which contain significantly lower amounts of hemoglobin, may also be vaporized.

Second, the laser energy at 980 nm also has slightly greater penetration of energy into the prostate gland, producing outstanding hemostasis.

Lastly, the irritative symptoms, which commonly occur post prostatic laser vaporization, have been very manageable. One of the concerns in the BPH community has been that if the energy is driven deeper into the prostatic tissue, these irritative symptoms will be increased in both severity and duration. To date, this has not been noted. However, the complication of delayed prostatic chip formation and slough has been noted, but with a change in operative technique, appears to have lessened in frequency.

This technology has also progressed in the last 2 years in both its power capabilities and its fiber-tip design. The early laser boxes generated significantly less power, and it was not until the 120-W device was produced that prostatic vaporization became a potentially efficient form of vaporization. Currently at the Cleveland Clinic Foundation (CCF), we are evaluating the 180-W device, which, in a limited number of cases, appears to be significantly more efficient at vaporization, thus shortening operative times. The fiber-tip designs are also under continued assessment and evaluation, and different tip designs may be more or less efficient and desired depending on certain prostatic characteristics. Presently, fiber tips of side-fire, end-fire, and Twister fiber™ are

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

available and under evaluation. Different fibers, with different characteristics, may have physical advantages in a variety of prostatic conditions, such as extensive middle lobe intravesical extension or bilobar hypertrophy with kissing lobes. This aspect of the technology remains under intensive investigation.

We continue to look at a variety of technologies for post brachytherapy and post cryotherapy urinary retention, for which no good therapeutic option currently exists. Again the 980-nm wavelength is currently under evaluation for these.

Preoperative evaluation

Proper patient selection prior to performing any BPH procedure remains of paramount importance. Every patient should be evaluated with a focused history and physical exam, including a digital rectal exam. An assessment of American Urological Association (AUA) symptom score and quality-of-life score, urinalysis, free urinary flow rate, postvoid residual volume (PVR), prostate-specific antigen (PSA), when appropriate, and voiding diary should also be performed.

Urodynamics have a utility in assessing bladder function and confirming bladder outlet obstruction in men with LUTS. However, pressure flow studies in the management of LUTS and BPH are controversial and are currently not recommended for routine use. We currently recommend the use of these studies for patients who demonstrate repeated elevations in PVR levels or have a known or likely component of a neurogenic bladder.

Transrectal ultrasound can confirm prostate size and prostate anatomy for invasive therapy, and assess the presence of any intravesical component and size of the middle lobe, and the presence of prostate cancer, if indicated by the PSA, in concert with a prostate biopsy.

Endoscopic evaluation of the lower urinary tract is not recommended in an otherwise healthy male with an initial evaluation consistent with bladder outlet obstruction (BOO), unless the treatment alternatives being contemplated, such as 980-nm prostate laser vaporization, depend on the anatomic configuration of the prostate, or if hematuria is present [6].

Patients with ongoing treatment with anticoagulants, such as Aspirin, clopidogrel, and coumadin, may be treated. Whenever possible, we prefer to remove these anticoagulants for 5–7 days. However, treatment with the 980-nm laser, because of its excellent hemostatic properties, can still be performed if these agents are not able to be suspended for reasons of the patient's health.

Wavelength and fiber characteristics

The 980-nm diode laser has been recently introduced at a power between 120 and 200 W. As mentioned, the energy emitted at this wavelength is highly absorbed by both water and hemoglobin, thus combining the highly efficient tissue ablative properties with excellent hemostasis. However, one significant energy question remains up for debate. Does the increased depth of penetration of the 980 nm laser energy into tissue change its effect on clinical symptoms in humans, both in the short and long term? Conflicting results have been obtained in similar experimental animal studies. For example, *ex vivo* investigations on human cadaver prostates revealed a 2.09-mm coagulation zone for the 80 W KTP 532-nm laser, while the 980-nm diode laser showed a coagulation zone up to 3.5 times larger at 7.10 mm [5]. However, Wendt-Nordahl *et al*. reported a thinner coagulation zone (290.1 vs 666.9 µm, $P < .05$) and faster ablation rate (7.24 vs 3.99 g/10 min, $P < 0.05$) for the diode 980-nm laser at 120 W compared to KTP at 80 W in the isolated porcine kidney model [3]. Also, KTP at the 532-nm wavelength is only absorbed by hemoglobin, so the data extracted from a human cadaver prostate model, which is devoid of circulation, may be somewhat controversial. Thus, the clinical significance of the difference in depth of penetration remains controversial.

There currently are numerous different types of 980-nm fibers approved for human use. Side-fire fibers remain the most common form, however, both end-fire fibers and Twister fibers are increasing in popularity.

Anesthesia

While the vast majority of prostate laser vaporization using the 980-nm diode laser is performed in an ambulatory surgery or operative setting, there are anecdotal, nonpeer reviewed reports of these procedures being done in an office setting. This should be the case only in patients with small volume prostates and who are highly motivated to have the procedure performed in the office setting. Physicians have used their own discretion in choosing the office-based analgesia from among:

- Preoperative medications: antianxiolytics, anticholinergics;
- Perioperative medications: intravesical chilled lidocaine/marcaine solution, intraurethral lidocaine, anticholinergics;
- Postoperative medications: alpha-blockers, nonsteroidal anti-inflammatory drugs (NSAIDs).

Also available are local anesthetic blocks, prostate blocks, and pudendal nerve blocks.

Office-based analgesia generally does not include intravenous sedation, but if applied, there should be monitored anesthetic support.

Most commonly, these procedures are done under a spinal or general anesthetic. Intubation is often not necessary, but this decision should be made in conjunction with the anesthetic team.

Procedure

While a variety of techniques have been reported in the literature, the technique described is the one we have found to be the easiest to learn and to teach to residents. The patient is placed in the dorsal lithotomy position and is sterilely prepped and draped. Preoperative antibiotics are administered. A continuous flow cystoscope with a 30º lens is carefully passed through the urethra into the bladder. We personally prefer a short beaked 23F cystoscope, as this reduces urethral trauma and allows the prostate to fall into the urethral lumen, facilitating vaporization. Normal saline is used for the irrigant. The visualization is adequate with saline and this will prevent hyponatremia in the rare event of a prostatic or bladder perforation. The laser fiber is extended just outside the field of view with careful attention to ensure that all markers on the laser fiber are visualized at all times, so that the fiber is not retracted into the scope and therefore avoiding potential cystoscope or lens damage.

The fiber is then placed in a near contact position. This will allow efficient vaporization of tissue, but preserve the integrity of the fiber tip, allowing longer vaporization. Excellent saline flow and visualization is essential for the ease of this procedure and thus, we begin the procedure by vaporizing the prostatic intravesical extension and circumferentially around the bladder neck. Any small bleeding vessels are immediately cauterized by revaporizing the bleeding area with the laser energy. Moving the laser fiber a little further away from the tissue will often help to control these bleeding points. Once the bladder neck has been opened, a wide groove is created from the 5 and 7 o'clock positions at the bladder neck to the level lateral to the verumontanum. The lateral lobes, ceiling, and floor of the prostate are then completely vaporized. Hemostasis is maintained. Once the procedure is completed, the scope is removed, and a 22F Coude catheter is placed. The patient is sent home on the same day, usually 2–4 h postoperatively, and if the urine is clear, the catheter is removed on the morning of postoperative day 1.

Results

There currently are limited results published in peer-reviewed journals and only short-term follow-up of these patients is available. Ruszat *et al*. reported that the 980-nm laser (Limmer Laser, Berlin, Germany; 132 W, side-fire fiber) was safe and effective in treating prostatic tissue [7]. Fifty-five men with a mean age of 72.3 years and an average prostate size 64.7 g were evaluated at baseline and 6 months postoperatively. Symptom score improved from 18.7 to 4.5, quality-of-life score improved from 3.2 to 0.8, maximum flow improved from 10.7 to 15.8 mL/s, PVR improved from 180 to 26 mL, and PSA levels dropped from 4.3 to 1.8 ng/mL. No significant hematuria was noted intraoperatively or postoperatively.

Erol *et al*. published their prospective series of 47 men treated with the 980-nm laser (Biolitec AG, Jena, Germany, 132 W, side-fire fiber) [8]. Their mean age was 65.4 years and average prostate size 51 g. Patients were evaluated at baseline and 6 months postoperatively. Symptom scores improved from 21.93 to 9.87, quality-of-life score improved from 4.19 to 2.15, maximum flow rate improved from 8.87 to 18.27 mL/s, PVR improved from 115 to 48 mL, and PSA levels dropped from 2.54 to 1.77 ng/mL. Once again, no significant intraoperative bleeding was encountered.

Lastly, Chen *et al*. recently reported their results on 55 patients treated with the 980-nm laser (Limmer Laser, 200 W, side-fire fiber) [9]. The average patient age was 72.7 years and mean prostate size 66.3 g. Patients were evaluated at baseline and 6 months postoperatively. Symptom score improved from 20.1 to 4.9, quality-of-life score improved from 5.1 to 2.2, maximum flow rate increased from 5.5 to 19.2 mL/s, PVR decreased from 173 to 21 mL, and PSA dropped from 5.1 to 2.1. No intraoperative or postoperative bleeding was reported.

Complications

All is not perfect, however, with this procedure. Numerous bothersome complications were reported in all studies, some of which required secondary procedures. Ruszat *et al.* reported immediate complications of dysuria in 24%, and transient urge incontinence in 7% of patients [7]. During follow-up there was a concerning bladder neck contraction rate of 15% leading to bladder neck incisions in all patients. An additional 18% of patients complained of persistent or recurring obstructive voiding symptoms. These patients thus had an indication for conventional TURP.

In contrast to these results, Erol *et al.* reported no secondary surgical procedures in their series, but did report a retrograde ejaculation rate of 31%, irritative symptom rate of 23%, and a low percentage of temporary urinary retention or incontinence [8].

Chen *et al.* presented a complication profile of transient urge incontinence in 14.5%, sloughed tissue in 14.5%, recatheterization in 10.9%, and reoperation in 7.3% [9].

Special circumstances

At the CCF, we have assessed at the 980-nm laser for the treatment of men post brachytherapy who developed urinary retention. In this group, we also have found that a significant number of repeat procedures need to be

performed secondary to the development of bladder neck contractures or clinically significant sloughed tissue obstruction. Discussion of these potential complications should be mandatory in this complicated patient group.

Conclusions

The 980-nm laser is a viable option in the treatment of BPH. This technology vaporizes tissue efficiently, has excellent hemostasis, and is as well tolerated perioperatively from the symptoms of urinary urgency and frequency as any other vaporization device. Its drawback may be the delayed slough of prostatic tissue as a result of the deeper penetration of energy into prostatic tissue.

CHAPTER 127
Holmium Laser Therapy of the Prostate

Hazem M. Elmansy & Mostafa M. Elhilali
Division of Urology, McGill University, Montreal, QC, Canada

Introduction

Transurethral resection of the prostate (TURP) has been the reference standard for the treatment of benign prostatic hyperplasia (BPH); however, TURP has an important mortality rate of 0.2–2.5%, immediate postoperative morbidity rate of 13–24%, including bleeding requiring blood transfusion (0.4–6.4%) and TUR syndrome (0.8–2%), and a retreatment rate of 2.3–4.3% within 12 months [1, 2]. This perioperative morbidity of TURP has been the driving force behind the development of several minimally invasive treatments of symptomatic BPH. Laser prostatectomy was first introduced in 1986 and gained popularity after the introduction of the side-firing fiber [3].

The ongoing refinements of laser technology over the past decade hold great promise and have resulted in effective laser applications in the surgical treatment of symptomatic BPH. Laser therapy provides several advantages over standard TURP, including the absence or minimization of complications, such as hyponatremia (TUR syndrome), bleeding, hospitalization, catheter time, and bladder irrigation, with no prostate size limitation. The use of normal saline with laser surgery eliminates the risk of TUR syndrome. The unique hemostatic properties of lasers result in almost bloodless removal of prostatic adenoma, significantly less morbidity and mortality compared to TURP, and a decrease need for blood transfusion and bladder irrigation [4].

Many efforts have been made to identify alternative surgical techniques providing comparable functional results to TURP, but with less morbidity and higher perioperative safety [5]. However, the most frustrating aspect about the use of minimally invasive techniques is the high rate of recurrence and the need for retreatment over time [6].

The holmium (Ho) laser has been associated with strong clinical evidence for its effectiveness in many applications in urology, such as incision of ureteral stricture, lithotripsy of urinary calculi, ablating superficial urothelial tumors, bladder neck incision (BNI), and surgical management of BPH [7–11].

The combination of the Nd:YAG laser with the Ho:YAG laser was used early to vaporize and coagulate tissue using a technique known as combination endoscopic laser ablation of the prostate (CELAP). The initial experience of this technique was first reported by Gilling *et al*. who found the use of the Nd:YAG laser lead to a longer catheterization time, delayed symptom improvement, and high recatheterization rate (26%). These side effects limit the usefulness of this technique, and CELAP has been replaced by the holmium-only technique [12, 13].

Since its first use in 1994, different techniques using the holmium laser wavelength have been used in the surgical management of BPH: holmium laser ablation (HoLAP), resection (HoLRP), and enucleation of the prostate (HoLEP).

Physics

Every new laser technology has specific advantages; however, its physics may result in significantly different outcomes. The holmium:yttrium–aluminum–garnet

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

(Ho:YAG) laser emits a pulsed, invisible infrared beam with a wavelength of 2140 nm, which is absorbed strongly by water (which constitutes 60–70% of the prostate). The depth of penetration is 0.4 mm, which predominantly causes vaporization without a deep coagulation zone when used with a side-firing fiber, and provides a precise incision and enucleation while maintaining hemostasis when used with an end-firing fiber. Energy absorption by the irrigant forms a vapor bubble around the laser fiber tip and this results in a microexplosion, causing a jackhammer effect that can cut tissues or disintegrate stones when in close contact to the target tissue [14]. If direct contact is not adequately maintained, laser efficiency will be reduced due to consumption of energy in the formation of vapor bubbles.

Surgical indications

Patients with lower urinary tract symptoms secondary to BPH causing bladder outlet obstruction are good candidates for holmium laser prostatectomy. HoLAP or HoLEP can treat glands of small-to-moderate size (<60 g), but larger glands are best treated by HoLEP.

Patients with more comorbidities or on anticoagulant medication are treated effectively with the holmium laser even while continuing their medications [15] In addition, the physical properties of holmium allow simultaneous transurethral cystolithotripsy during holmium laser prostatectomy [16].

Hip mobility problems secondary to degenerative disease, which will not allow patients to be placed in an adequate lithotomy position, are a relative contraindication for HoLEP.

Surgical management of benign prostatic hyperplasia

Holmium laser bladder neck incision

This technique uses the holmium laser energy to perform single or bilateral incision of the bladder neck. This is best suited to small glands with an elevated bladder neck and short prostatic urethra. Holmium laser bladder neck incision (HoBNI) can be performed as a catheter-free outpatient procedure. Cornford *et al*. confirmed the effective and durable results of this technique: at 2-year follow-up, the mean maximum renal flow rate (Qmax) increased from 9.7 to 18.2 mL/s [17].

Holmium laser ablation of the prostate

In 1994, HoLAP using a side-firing fiber was the first procedure using the holmium wavelength alone for laser prostatectomy. HoLAP is easy to learn, but it requires a longer operating time [18, 19]. For HoLAP, a 80–100-W holmium laser generator and 550-μm side-firing laser fiber are frequently used. The settings for HoLAP range from 2 J and 50 Hz to 3.2 J and 30 Hz, without the need for any tissue retrieval instruments. HoLAP is performed with the patient under general or regional anesthesia and normal saline is used as the irrigant.

Vaporization of the prostate usually starts at the bladder neck using the side-firing laser fiber to make a BNI at 5 and 7 o'clock; then the laser fiber is gently moved over the surface of the obstructed lobe towards the apex of the prostate proximal to the verumontanum. The end-point of the laser procedure is a TURP-like cavity lined by capsular fibers.

In a randomized trial comparing HoLAP and TURP in men with prostates smaller than 60 mL, the subjective and objective improvements in both group were similar at 1-year follow up. However, the advantages of HoLAP over TURP included less dysuria and bleeding, and shorter hospital stay and catheter time, without need for any irrigation [20].

HoLAP achieves durable relief of bladder outlet obstruction and urinary symptoms. At 7-year follow-up of 34 patients who underwent HoLAP, there was an 83% improvement in Qmax, a 47% decrease in symptom score, reoperation rate of 15%, and recatheterization rate of 9% [21].

McGill University Health Center (MUHC) reported on 109 patients who were randomly assigned to undergo either HoLAP or photoselective vaporization of the prostate (PVP) with a follow-up period of up to 4 years. The early results of this study confirmed that both techniques are safe and effective in small-to-moderate size prostates; however, HoLAP required a longer operating time by 14 min [19] Subjective and objective voiding parameters showed significant improvement, lasting for up to 3 years and confirming the long-lasting and durable effects of both techniques. At 3-year follow-up, mean International Prostate Symptom Score (IPSS) improved by 69.5% and 63.6% and mean Qmax increased by 164% and 190% in the HoLAP and PVP groups, respectively. The overall retreatment rate for urethral stricture, bladder neck obstruction, and residual adenoma was 15.8% versus 19.3% in the HoLAP and PVP group, respectively. The reduction in prostate-specific antigen (PSA) was 47.8% and 28.6% in the HoLAP and PVP groups, respectively, which reflects the incomplete removal of adenomatous tissue. The incidence of retrograde ejaculation in sexually-active patients was 12 of 33 (36.3%) in the HoLAP group compared to 13 of 30 (43.3%) in the PVP group. There was no significant difference between preoperative and postoperative sexual function.

Kumar reported on a series of 17 patients with a prostate volume greater than 80 mL treated with a 100-W

holmium laser [22]. He noted that the mean percentage improvement in the American Urological Association (AUA) symptom score and Qmax was 70% and 217%, respectively, with a 55% reduction in prostate volume. In addition, the incidence of bladder neck contracture was 5% with no stricture urethra reported; however, the small number of patients in this study was a limiting factor.

The vaporization techniques are best suited to small or moderate sized prostates; larger prostates will necessitate a much longer operative time and the use of more than one fiber, with more patients having to undergo reoperation. Thus, for large prostates, HoLAP may not be economic when compared with standard TURP [22]. Further studies are needed to assess the effectiveness, safety, and durability of this technique in the management of large-sized prostates.

A controversial issue related to HoLAP when compared to TURP is the lack of tissue for histopathologic examination, which could lead to diagnoses of prostatic carcinoma being missed. Therefore, it is mandatory to perform a thorough evaluation of patients with an elevated PSA level or abnormal digital rectal examination (DRE), with transrectal ultrasound (TRUS)-guided biopsies prior to the intervention. It is also mandatory to continue postoperative PSA and DRE surveillance.

Holmium laser resection of the prostate

Before the development of the morcellator, Gilling *et al*. developed a technique that aimed to resect prostatic tissue by the holmium laser, similar to TURP. The resected pieces were small enough to be retrieved by a modified resectoscope loop or Ellik evacuator.

HoLRP starts with bilateral incision to define the depth and amount of tissue to be removed. The next step is to join the two incisions just in front of the verumontanum to undermine the median lobe and deposit it into the bladder. Incisions at 1 and 11 o'clock position over the entire length of the prostate are needed to define the upper margin of the excision of the lateral lobes. Dissection occurs precisely in the plane between the adenoma and capsule in a retrograde fashion until only a bridge of tissue remains at the bladder neck [11]. The technique of HoLRP produces a cavity identical in appearance to TURP, but with a relatively bloodless procedure that results in a short catheter time, immediate functional improvement, and minimal postoperative irritative symptoms. In 1996, Gilling *et al*. reported in a series of 84 patients that mean AUA score improved from 21.3 preoperatively to 7.6 at 1 month and 4.1 at 3 months. The mean Qmax increased from 7.5 mL/s preoperatively to 17.8 mL/s at 1 month and 19.3 mL/s at 3 months. Two patients (2%) required bladder irrigation for significant hematuria perioperatively and four patients (5%) required recatheterization; a few patients reported mild irritative urinary symptoms [11].

A prospective randomized study in 1999 compared HoLRP to TURP for the surgical management of symptomatic BPH [23]. Both techniques resulted in significant improvements in symptom score, quality-of-life (QoL) score, Qmax, and postvoid residual urine (PVR). Operative time was significantly longer in the holmium group but perioperative morbidity, catheter time, nursing contact time, and hospital stay were significantly less for HoLRP compared to TURP. The long-term results of this randomized trial in 2004 confirmed the long-lasting effect and durability of this technique in terms of symptom score and flow rate [24].

Holmium laser enucleation of the prostate

There is a persistent interest in HoLEP as the new gold standard for the surgical management of BPH in prostates of any size, replacing open prostatectomy and TURP [25]. Results from many studies, including randomized trials and systematic reviews, have confirmed the effectiveness and durability of HoLEP, as evidenced by functional outcomes, PSA data, TRUS, weight of tissue resected, and urodynamic parameter [26–31]. HoLEP has allowed patients who traditionally required open prostatectomy the alternative of being treated endoscopically with minimal blood loss, and short catheterization time and hospital stay [32]. It also provides optimal tissue for histopathologic assessment.

HoLEP reproduces the removal of the obstructing prostatic tissue with a true anatomic surgical enucleation of the adenoma, identical to using the index finger in open prostatectomy. The introduction of the tissue morcellator facilitates faster removal of the prostatic adenoma enucleated from the bladder.

Instruments and technique

The equipment consists of a 26F continuous flow resectoscope sheath with a modified inner sheath and a terminal bridge, through which 5F or 7F catheters are introduced to hold and stabilize the end-firing laser fiber. The high power pulsed 80–100-W holmium laser unit (Lumenis, Santa Clara, CA, USA) is frequently used with a 550-μm end-fire laser fiber. The laser is set at 2 J and 40–50 Hz. The Versacut morcellator (Lumenis) is introduced through a long nephroscope and an adaptor (Karl Storz, Tuttlingen, Germany) is used for tissue retrieval.

The enucleation procedure has been well described by Gilling [32] and Fong and Elhilali demonstrated the procedure in a video article [33]. Recently, we introduced some technical refinements in the HoLEP technique that

may decrease the operative time and learning curve; these are available for review online [34].

The advantages of this technique include an almost bloodless field, allowing better vision with simultaneous coagulation of all bleeding vessels. Moreover, the dissection can be sharp or blunt. Three-dimensional awareness and hand–eye coordination are mandatory in this technique. The visibility in HoLEP, compared with standard TURP, is much better because of the bloodless field and the greater image magnification.

Two techniques are used for HoLEP based on the anatomy and size of the middle lobe. In general, a two-lobe technique should be attempted whenever there is only a single or no deep groove at the 5 or 7 o'clock positions of the bladder neck (as in the majority of cases). This lowers the risk of undermining the trigone. The three-lobe technique is used only when there is a large median lobe with deep grooves on both sides.

Enucleation is done using a combination of blunt and sharp dissection in a retrograde fashion. The blunt enucleation is achieved by using the tip of the scope, just like using a finger, to separate the adenoma from the surgical capsule in a technique similar to the traditional retropubic prostatectomy but in a retrograde manner. The operator should always use a rotating movement to follow the contour of the prostate and care must be taken to avoid using excessive force so as not to unnecessarily stretch the external urinary sphincter. Blunt enucleation should be avoided if the tissues do not separate easily. Instead, the laser should be used to cut any attachments. The proper plane can be identified from its appearance, as well as from the ease with which the tissues separate (see Video 1.1). A modification we are proposing is that when the adenoma is separated laterally and the anterior aspect of the prostate is reached, the dissection is extended across the midline in order to facilitate the later separation of the two lobes in the midline anteriorly when the 12 o'clock incision is performed, eliminating any guess work about the depth needed (see Video 1.2). Once the anterior incision is made, the only attachment that the adenoma has should be the apical mucosal strip at the level of the urinary sphincter. This is carefully incised using short energy bursts at settings of 1.5 J at 30 Hz for an energy level of 45 W, to minimize the risk of thermal damage to the sphincter (see Video 1.3).

The lateral lobes are gently pushed into the bladder. Finally, morcellation of the prostate is performed inside the bladder. Special emphasis is placed on achieving excellent hemostasis before starting morcellation because the visibility with the indirect nephroscope is not as good as with the cystoscopic lens. When coagulating a bleeding vessel, the laser fiber is unfocussed but directed end-on towards the bleeding point. A whitening of the tissue around the vessel can often be used as an indicator of adequate coagulation. Morcellation is one of the most critical steps of the procedure and is often considered potentially dangerous. In order to avoid complications, two principles need to be strictly observed. First, the patient's bladder should be adequately distended. This is achieved by ensuring that the patient's abdominal muscles are relaxed and that the irrigation inflow is not interrupted. Second, the morcellation process should always be performed under direct vision. This is achieved by having adequate hemostasis and by keeping the engaged piece directly in front of the lens of the nephroscope, with the nephroscope tip and cutting blades in the middle of the bladder (see Video 1.4)

Before the availability of tissue morcellators, some authors performed a mushroom technique. Fragmentation of the lobes was performed by traditional electrocautery loop resection whilst the devascularized lobes were still connected to the surgical capsule by a narrow pedicle [30].

Postoperative care

At the end of the procedure, a 20–22F, 30-mL balloon two-way Foley catheter is inserted. Sometimes a stylet is needed to insert the catheter. The catheter is fixed to a Y-connector, which is used to deliver intermittent irrigation to the bladder if needed in the recovery room. Rarely, a three-way catheter and continuous bladder irrigation are used. The catheter is removed on the next morning unless otherwise indicated and the patient is discharged. Some urologists discharge patients on the same day without a catheter, but this practice is usually limited to HoLAP or small volume HoLEP.

Safety

Recent reports on HoLEP have confirmed its safety for different prostate sizes, with no size limits, and with low morbidity and short catheterization time and duration of hospitalization.

Naspro *et al*. performed a randomized study comparing HoLEP to open prostatectomy in 80 patients (41 vs 39 patients, respectively) with a prostate size greater than 70, g [26]. HoLEP was shown to be safer than open prostatectomy in the perioperative period, requiring a lower number of blood transfusions (4% vs $P < .001$) in addition to a shorter catheterization time (1.5 vs 4.1 days, $P < 0.001$) and hospital stay (2.7 vs 5.4 days, $P < 0.001$). However, time in the operating room was significantly longer for the HoLEP group (72 min) than the open prostatectomy group (58 min) ($P < .0001$). Furthermore, the authors reported a 7.3% bladder mucosal injury rate in the HoLEP, and the early acute

urinary retention rate was 12.1% (vs 5.1%in the OP group, P = 0.11).

Shah *et al*. performed a prospective study evaluating the perioperative complications in 280 patients undergoing HoLEP [35]. Blood transfusion was required during HoLEP in one patient; other complications included capsular perforation (9.6%), superficial bladder mucosal injury (3.9%), and ureteric orifice injury (2.1%). A blood transfusion was needed after HoLEP in 1.4% of patients with clot evacuation in 0.7% by cystoscopy.

Bladder mucosal injury is a potential complication related to morcellation, and can be avoided by effective hemostasis and adequate bladder distention prior to morcellation. Care must be taken not to engage the bladder mucosa during the suction phase. Rieken *et al*. recently extensively reviewed data published between 2003 and 2006 [36]. They reported capsular perforation rates ranging from 0.3% to 10%; these were usually small capsular lacerations that did not require further management. Bladder injury is reported in 0.5–18.2%, with superficial mucosal injury requiring no additional treatment in most cases. Rates of superficial ureteric orifice injury not requiring insertion of a ureteral stent or nephrostomy tube ranged from 1.0% to 2.1% and incomplete morcellation from 1.9% to 3.7%, and cardiac events were reported in up to 1.2% of patients undergoing surgery. The authors demonstrated a correlation between the incidence of such complications and the level of experience of the surgeon. In addition, they found that prostate size had no statistically significant influence on intraoperative complications: capsular perforations were more likely associated with smaller prostates, while injury of the ureteric orifice occurred mainly during resection of large median lobes protruding into the bladder.

TURP in patients with BPH on anticoagulant therapy is frequently avoided due to the higher perioperative morbidity. It is also associated with an increased incidence of perioperative hypercoagulability state, with an overall 8% incidence of deep vein thrombosis after TURP [37, 38]. HoLEP has been shown to be a safe and effective therapeutic modality in patients on anticoagulation with symptomatic BPH refractory to medical therapy. Elzayat *et al*. performed a retrospective study of 83 patients who were on chronic oral anticoagulant therapy or had bleeding disorders and underwent HoLEP with a mean prostate size of 82.4 mL [15]. A total of 14 patients underwent HoLEP without oral anticoagulant withdrawal, 34 underwent surgery with low molecular weight heparin substitution, and 33 stopped anticoagulants a few days before surgery and restarted them immediately after surgery, including eight on antiplatelet therapy. One patient required intraoperative platelet transfusion and seven required blood transfusion early in the postoperative period due to hematuria coinciding with restarting oral anticoagulant therapy. There were no major operative or postoperative complications, or thromboembolic events.

Early efficacy

HoLEP produces immediate and sustained improvement of objective and subjective outcomes similar to both open prostatectomy and TURP. The pre- and postoperative urodynamic assessment has confirmed that the relief of obstruction with HoLEP is superior to, or at least equivalent to, TURP and open prostatectomy [27, 30, 39].

Wilson *et al*. compared the functional outcomes of HoLEP to TURP in a randomized study of patient with a prostate size of 40–200 g. At 1-month follow-up, functional outcomes in terms of AUA score (8.6 vs 5.7) and Qmax (22.3 vs 18.4 mL/s) were observed in the HoLEP and TURP groups, respectively [27]. The improvement in functional outcomes was maintained for up to 24 months. In 2007, Ahyai *et al.* published interesting data regarding the efficacy of HoLEP compared to TURP [28]. A total of 200 patients with a prostate volume of less than 100 mL were prospectively randomized to HoLEP or TURP and followed up for up to 3 years. At 2- and 3-year follow-up, HoLEP micturition outcomes compared favorably with those of TURP. The AUA score was significantly better at 2 years postoperatively in the HoLEP group (1.7 vs 3.9, $P < .0001$) and similar at 3 years (2.7 vs 3.3, $P = .17$). PVR was significantly better at 2 years (5.6 vs 19.9 mL, $P < .001$) and 3 years (8.4 vs 20.2 mL, $P = .012$) postoperatively in the HoLEP patients. However, Qmax was similar in the HoLEP and TURP groups at 2 years (28.0 vs 29.1 mL/s, $P = 0.83$) and at 3 years (29.0 vs 27.5 mL/s, $P = 0.41$) postoperatively.

In comparing HoLEP to open prostatectomy, Naspro *et al*. demonstrated equivalence in terms of improvement in obstruction, starting with the 3-months follow-up and reaching a plateau at the 24-month follow-up [26]. At 24 months, Qmax had improved to clinically normal levels in both the HoLEP and open prostatectomy groups (19.19 vs 20.11 mL/s, $P < 0.9$, respectively).

Kuntz *et al.* confirmed the previously reported data on large prostates in a randomized trial in patients with prostates larger than 100 g [40]. Both HoLEP and open prostatectomy resulted in effective and long-lasting postoperative improvements in symptom scores, Qmax, and PVR. The differences between HoLEP and open prostatectomy in functional outcomes were not significant at each time point during follow-up.

Early postoperative stress incontinence occurs as a rare event after HoLEP and is reported in around 2% of cases, which is comparable with results from TURP and open prostatectomy [28, 41].

Urinary retention

Patients with urinary retention represent a particular challenge to urologists, as they often experience inferior functional outcomes and a higher complication rate when compared to patients without urinary retention. Peterson *et al*. retrospectively evaluated 164 patients in urinary retention treated by HoLEP [42]. Mean duration of urinary retention was 28.9 days (range 2–365 days). Their results confirmed the safety and reliability of this procedure for treating urinary retention in men with large prostates. All patients were able to void following treatment and remained catheter free. Mean urine flow rate was 26.7 mL/s (range 4.3–54.8 mL/s) and mean PVR was 32.5 mL (range 0–150 mL). The outcome for patients with chronic urinary retention and hypotonic bladder may be less satisfactory.

Late efficacy and durability

Sufficient data prove HoLEP's durability for most prostate sizes at long-term follow-up (Figure 127.1). Gilling *et al*. recently published 6-year data, demonstrating persistent reductions in IPSS scores (8.5 vs 25.7) and QoL score (1.8 vs 4.9), and improvements in Qmax (19 vs 8.1 mL/s), with a 92% overall satisfaction rate with the results [29]. Elzayat and Elhilali confirmed that Qmax increased by 204%, PVR declined by 81%, and IPSS decreased by 67.6% during 5-year follow-up [43]. The improvement in outcome parameters was durable and the late complication rate was very low.

Kuntz *et al*. reported their 5-year follow-up results in a randomized clinical trial comparing HoLEP to open prostatectomy [30]. Interestingly, mean AUA score was 3.0 in both groups ($P = 0.98$), mean Qmax was 24.4 mL/s in both groups ($P = 0.97$), and PVR was 11 mL in the HoLEP and 5 mL in the open prostatectomy group ($P = 0.25$). Late complications included urethral strictures and bladder-neck contractures; the overall reoperation rates were 5% in the HoLEP and 6.7% in the open prostatectomy group ($P = 1.0$). BPH did not recur in any patient.

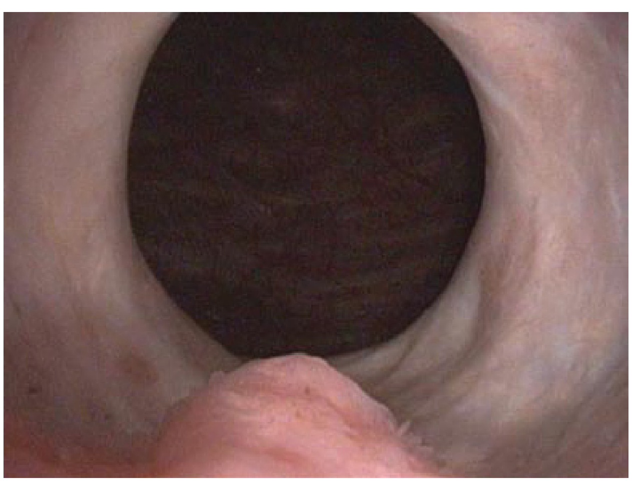

Figure 127.1 Cystoscopy 6 years post HoLEP.

Urethral strictures have been reported in 1.4–4.1% of cases and bladder neck contractures in 0–5.4% (Table 127.1). The reintervention rate due to residual tissue is very low (0-5.4%) over a follow-up period of up to 7 years [43, 44].

Prostate-specific antigen reduction

Measurement of PSA may be a useful surrogate tool for the objective assessment of the amount of residual prostatic tissue following different therapies for BPH. It has been reported that serum PSA level is markedly reduced after open prostatectomy or transurethral surgery, as the transition zone is the major source of PSA production. Stamey *et al.* reported the changes in PSA after open prostatectomy or transurethral procedures for the treatment of BPH [45]. There was a mean decrease in PSA of 95% in the open prostatectomy group and of 84% in the TURP group (73 men). Others have confirmed a mean percentage PSA reduction of 70– 75% after TURP [46].

HoLEP produces a significant reduction in PSA that correlates well with the weight of adenoma resected (Figure 127.2). Tinmouth *et al.* examined PSA data before and after HoLEP from two institutions performing high volumes of this procedure in a retrospective evaluation of 509 patients [47]. The average weight of adenoma resected was 49.8 g (range 5–300 g) in the McGill group

Table 127.1 Causes of retreatment following treatment with HoLEP.

	Urethral stricture (%)	Bladder neck contracture (%)	Residual adenoma (%)
Naspro *et al.* [27]	2.8	5.4	5.4
Wilson *et al.* [28]	3.2	0	0
Elzayat *et al.* [43]	1.6	0.8	4.2
Ahyai *et al.* [29]	4.1	3.1	1
Shah *et al.* [35]	2.1	0.4	0
Gilling *et al.* [30]	1.4	0	1.4
Kuntz *et al.* [31]	3.3	1.7	0

Figure 127.2 Adenoma weight on Transurethral ultrasound (TRUS) 6 months after HoLEP (adenoma weight 24 g, compared with 140 g preoperatively. The entire resected channel through the prostatic urethra can be well identified after HoLEP (arrow).

and 90.4 g (range 7.9–312 g) in the Methodist Hospital group, and the mean decrease in PSA 81.7% and 86%, respectively.

Elmansy *et al*. evaluated 335 patients treated with HoLEP between 1998 and 2006 in a longitudinal study [48]. They found that the mean PSA dropped from 5.44 to 0.91 ng/mL and the mean PSA reduction was 75.4%, indicating that HoLEP is an effective technique in near complete adenoma resection. Moreover, this percentage reduction in PSA was maintained for up to 7-year follow-up, suggesting that the reduction in gland size after HoLEP is durable and more complete, which could explain the lower reoperation rates previously reported for residual tissue. In addition, they proposed that if the reduction of PSA after HoLEP is less than 50%, closer follow-up with PSA measurements every 3–6 months for the first 2–3 years is indicated to allow earlier detection of prostate cancer.

Sexual function

Only two randomized clinical trials have specifically evaluated sexual function following HoLEP. Briganti *et al*. evaluated 120 patients in a prospective two-center randomized trial comparing the impact on sexual function of HoLEP versus TURP [49]. According to the International Index of Erectile Function (IIEF) score, HoLEP and TURP had a similar limited impact on erectile function with a slight but nonsignificant improvement. It seems that the cessation of preoperative medications, such as finasteride and alpha-blockers, and/or the improvements in the functional urinary outcomes may be related to this improvement. Both techniques significantly decreased the score for the orgasmic function domain, due to retrograde ejaculation in 78.3% in both groups after 2-year follow-up. Moreover, no significant differences were found between preoperative and postoperative sexual function regarding intercourse satisfaction, sexual desire, and overall satisfaction.

Comparing HoLEP to open prostatectomy, Naspro *et al.* were able to demonstrate equivalence in terms of sexual function after both procedures [26].

Gilling *et al*. reported a 76% rate of retrograde ejaculation after HoLEP that lowered the orgasmic function domain without affecting the other IIEF domains, such as intercourse satisfaction, sexual desire, and overall satisfaction, confirming that retrograde ejaculation is less likely to have a negative impact on overall sexual life satisfaction [29].

Learning curve

While HoLAP is a simple and easy to learn technique that can be mastered in a few cases, adoption of HoLEP has been limited by its steep learning curve, a limitation often stated by the urologists [33]. HoLEP requires longer training than standard TURP. Extensive experience with transurethral surgery and the supervision of an experienced urologist are mandatory to master this technique. In particular, the initial apical enucleation and incision of anteroapical mucosal attachments of the lateral lobes are difficult to master.

Elhakim and Elhilali presented the initial experience of a senior urology resident with HoLEP. He treated 27 patients with a mean prostate size of 54.8 g under the supervision of an experienced urologist. His overall results were comparable with those reported for the supervisor. They found that an average of 15–20 cases is needed for the trainee to feel confident with the technique [50].

However, Shah *et al*. reported that an endourologist inexperienced with HoLEP can perform the procedure with reasonable efficiency after about 50 cases, with an outcome comparable to that of the experts [51]. A higher incidence of complications, including capsular perforation and stricture urethral stricture, was seen in first 50 cases, with enucleation efficiency reaching a plateau after 50 cases. There was no significant difference in the functional parameters between the first cases and the last 62 cases.

Seki *et al.* also showed that significant relief of symptoms and urodynamic parameters can be achieved even very early in a urologist's experience [52]. However, the

authors concluded that enucleation efficiency was likely to be associated with a learning curve of up to 50 cases, as the average enucleation efficiency was 0.29 g/min for the first 10 cases but 0.75 g/min by the 70th case.

Elzayat *et al*. performed a retrospective study evaluating 118 patients who underwent HoLEP and compared the results for the first 50 patients with a later group of patients [43]. There was no significant difference in the enucleation and morcellation times in both groups. However, the retreatment rate after 5 year follow-up in the earlier group was higher (8% vs 1.4%).

New practitioners need a high volume cases to become familiar with this technique. Urologists who do not treat enough cases to maintain a reasonable operative frequency will have a longer learning curve that could be reflected in their complication rate [53]. We feel that it is also important in the learning process for the procedures to be carried out at short intervals, so as to build on experience rather than starting from the beginning each time.

Cost

HoLEP has been shown to be more cost-effective than open prostatectomy. Salonia *et al.* analyzed the inpatient costs of HoLEP compared to open prostatectomy [54]. They found that the hospitalization cost of HoLEP was 9.6% less than that for open prostatectomy. The cost reduction is mostly related to the shorter hospital stay and the significant reduction of blood loss, which eliminates the need for blood transfusion. In addition, one advantage of HoLEP that could affect the final cost is that the same fiber can be used up to 20 times.

Fraundorfer *et al* demonstrated that HoLEP was more cost-effective than TURP at 1-year follow-up, considering perioperative data and complication rate with the subsequent unplanned clinic visits and readmissions [55].

Histology and morcellation

The vaporization and coagulation effects of HoLEP and use of morcellation raise a concern about the ability of the histopathologist to accurately assess the adenoma specimen. In a prospective study comparing histologic findings of HoLEP and TURP, Naspro *et al*. confirmed that general prostatic architecture is maintained in the majority of HoLEP histologic specimens without affecting the ability to detect incidental prostate cancer and prostatic intraepithelial neoplasia [56].

Conclusions

Different types of lasers have been used to perform laser prostatectomy and give comparable and durable result similar to TURP with minimal morbidity, short catheterization time, short hospital stay, and low reoperation rate with no significant complications. The holmium laser has been effectively used for many urologic applications.

HoLEP seems to offer the most favorable functional outcomes in terms of subjective and objective parameters with no prostate size limitation. Emerging data have confirmed this technique to be durable with an overall low reoperation rate. For other modalities, long-term follow-up and randomized comparative studies are still needed to confirm the effectiveness and durability of each technique.

CHAPTER 128
532-nm High-Power Transurethral Laser Prostatectomy

Bilal Chughtai, Melissa Laudano, Richard Lee & Alexis E. Te
Weill Medical College of Cornell University, New York, NY, USA

Introduction

Lasers have evolved from theory to practical application. One use is the treatment of symptomatic benign prostatic hyperplasia (BPH) via laser prostatectomy. Traditionally, the gold standard for treatment of BPH is the electrocautery-based transurethral resection of the prostate (TURP). TURP, however, is associated with several complications and side effects, including fluid absorption, electrolyte imbalance, intraoperative and postoperative bleeding, and inadequate resection. Laser therapy has several advantages over standard TURP, including technical simplicity and the absence or minimization of complications such as intraoperative fluid absorption, bleeding, retrograde ejaculation, impotence, and incontinence. Laser therapy may also result in a shorter hospital stay and recovery. Less bleeding and irrigant absorption theoretically allows laser prostatectomy to treat larger glands with less physiologic stress, suggesting a role for laser therapy in patients with a high burden of coexisting medical disease. Recent estimates suggest an increasing number of practicing urologists are in fact already performing laser prostatectomies on patients with symptomatic BPH. Furthermore, the techniques and lasers used for laser prostatectomy are constantly evolving. To fully understand the mechanism of laser interaction with prostate tissue, some basic laser principles must first be understood.

Laser physics

The word "laser" actually represents an acronym, standing for light amplification by simulated emission of radiation (LASER). An external energy source is used to excite electrons in a medium with an inherently large population of unstable electrons, causing the electrons to reach a higher energy state, called a metastable level. As the electrons return to ground state, they release an amount of energy equal to that initially absorbed, resulting in the spontaneous emission of photons [1–3] . Unlike normal white light, which is comprised of the entire visible electromagnetic spectrum, laser energy is monochromatic, i.e. all of its photons originate from the same energy level transition with both spatial and temporal coherence [1–3] . Additionally, laser rays are parallel to each other and hence do not converge or diverge unless reflected or focused by a lens or mirror. However, once transmitted through flexible fibers by internal reflection, the laser beam will become divergent as it exits the fiber.

Laser energy affects tissue by inducing coagulation, vaporization, or even a mechanical tearing of tissue [4]. Power directly influences the temperature level reached and the speed with which a surgical effect is achieved. Generally, a temperature of greater than 50°C is required to produce a coagulative effect, while a temperature of greater than 100°C is required to produce a vaporization effect. Medical laser sources usually possess a maximum power output of 20–100 W, although some newer sources can reach a power of 180 W.

Power density, defined as power per unit area (P/A), represents the most important parameter that expresses the strength of the laser at a fixed location. Fibers with narrowly divergent beams will have a much higher power density than fibers with widely divergent beams due to the difference in the size of target areas. As a

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

corollary, this also implies that maximum power density arises when the tip of a laser fiber is almost in contact with tissue, i.e. at the distance where divergence is minimized [1–3, 5, 6].

Laser–tissue interaction

Four major interactions occur when laser energy is applied to human tissue.

Reflection

Up to 50% of the incident energy of a laser beam is reflected away. After the initial reflection, the remaining energy is then transmitted through the tissue for a specific distance, depending upon the type of laser used as well as the particular type of tissue being treated. After absorption, the laser energy is then converted to thermal energy, or heat.

Scattering

As laser energy strikes the irregularities of a tissue surface, diffuse reflection, also known as scattering, occurs. Scattering may occur in either forward or backward directions. The amount of scatter that occurs depends on tissue characteristics such as water content, cell constituents, and pigments. Scattering also depends on the resonant absorption and re-emission of radiation by the atoms of the receiving tissue, as well as the diffraction or radiation of laser energy in directions away from the line of propagation. As a result of scattering, a laser beam does not merely continue to penetrate in a straight line but dissipates its energy within the surrounding area, beginning when it hits the first tissue interface and continuing to create a zone of heat along the path of the beam.

Penetration

Laser energy may alternatively penetrate tissue. The depth of penetration by laser energy depends on its wavelength and the composition of the receiving tissue. Penetration is often described by "extinction length," the depth of penetration of an incident beam beyond which only 10% of the initial beam energy is left, i.e. 90% absorption. Therefore, after one extinction length, 10% of the beam will penetrate further, whereas after two extinction lengths, 1% of the beam will penetrate further, and so on.

Absorption

Laser energy may finally be absorbed by tissue. Absorption of laser energy is often described by "absorption length," the depth of tissue through which 63% of the incident beam energy is absorbed. It is important to note that the different components of living tissue absorb different laser energy wavelengths in variable fashions. Water, constituting 75–85% of soft tissue, absorbs 532-nm laser energy very poorly, resulting in deep penetration of the laser beam into tissue. Pigments, such as hemoglobin, bilirubin, and melanin absorb 532-nm energy very efficiently. Finally, carbon, an abundant constituent of all living tissue, is a final breakdown product of pyrolysis and represents a strong absorber of all wavelengths of laser energy.

532-nm laser

The original 532-nm laser was a potassium–titanyl–phosphate (KTP)-based laser system that contained a KTP crystal through which a 532-nm wavelength was generated. This had a different interaction with prostate tissue from its parent, the neodymium:yttrium–aluminum–garnet (Nd:YAG) [7]. The 532-nm wavelength is selectively absorbed by hemoglobin, which acts as an intracellular chromophore. The 532-nm laser energy can be fully transmitted through aqueous irrigants into the cell where it is absorbed by hemoglobin, which is then rapidly heated, leading to vaporization of prostate tissue. The short optical penetration that is associated with this wavelength confines its high-power laser energy to a superficial layer of prostate tissue that is vaporized rapidly and hemostatically, with only a 1–2-mm rim of coagulation. The thin coagulation zone arises as a result of the quasi-continuous emission characteristics of the 532-nm laser. Typically, continual irradiation of a single point causes heat to diffuse into deeper tissue layers, causing coagulation wherever there is enough convection thermal energy for protein denaturation but insufficient energy for vaporization. These selective characteristics led to the use of the 532-nm laser in prostatectomy, coined "photoselective vaporization of the prostate" (PVP).

Historically, initial trials involved the comparison of the 532-nm KTP-based laser with the Nd:YAG laser in 41 canines [7]. Both techniques were hemostatic in nature, with no irrigant absorption detected. KTP laser vaporization produced a prostatic defect with a mean diameter of 3.0 and 2.4 cm at 2 days and 8 weeks postoperatively, respectively. Statistically smaller defects were produced by Nd:YAG laser vaporization (2.0 and 1.4 cm, respectively) and coagulation (0.5 and 0.9 cm, respectively). None of the dogs treated with KTP laser vaporization was incontinent or developed urinary retention postoperatively. The use of the KTP laser thus appeared safe and effective in small-scale animal series.

60-W data

Experiments with a higher power 60-W KTP laser began with both *in vivo* canine studies as well as cadaveric canine and human trials [8]. These studies proved the ability of the KTP laser to vaporize tissue while minimizing accompanying coagulation effects. The first human trials with the 60-W KTP laser were conducted in a series of 10 patients described by Malek *et al*. in 1998 [9]. No patients suffered postoperative TUR syndrome or urinary retention; in fact, all patients were catheter free within 24 h after the procedure. Patients experienced a significant improvement in maximum renal flow rate (Qmax) (142%) by 24 h postoperatively. Though the follow-up described was preliminary in nature, initial results have suggested enduring results in terms of Qmax, mean American Urological Association (AUA) symptom score, and mean postvoid residual urine (PVR) at the 3-month follow-up. Mean operative time was 29 min.

These original human trials with the 60-W KTP laser were followed by a larger series of 55 patients in 2000 [10]. The 2-year experience with the higher powered KTP laser again corroborated initial findings. Patients experienced statistically significant, enduring improvements in postoperative AUA symptom score (mean 14, 82% improvement), Qmax (mean 29.1 mL/s, 278% improvement), and PVR (27 mL, 75% improvement) at 2 year follow-up, comparing favorably with published results for conventional TURP. Mean operative time was 44 min. All patients in the series were catheter free 24 h after the procedure; none required recatheterization or experienced TUR syndrome. Hematuria was negligible despite the use of antiplatelet agents by many patients. These results demonstrated that prostatectomy with the 60-W KTP laser was as effective as conventional TURP, and in fact demonstrated postoperative complications comparable to TURP and even to other laser therapies, such as the holmium:YAG.

80-W data

Despite the effectiveness of the 60-W KTP laser in prostatectomy, its less-than-ideal speed of vaporization inherently limited the size of prostate that could be resected. The next logical improvement therefore lay in increasing the laser power to speed tissue ablation. It is interesting to note that to preserve a thin coagulation zone while maintaining high vaporization efficiency, a unique laser pulsing technology was incorporated into the 80-W higher power KTP laser system. A high frequency modulation of laser light generates a continuous stream of short micro-pulses with a duration of 4.5 ms and a peak power of 280 W, i.e. 3.5 times the average laser power of the regular 80-W laser. The short duration of the micro-pulses does not allow time for heat to diffuse from the superficial layer, thus confining energy to a small volume of tissue, a situation referred to as thermal confinement. As each micro-pulse generates a very fast temperature increase inside tissue, the tissue water is not only rapidly vaporized but the surrounding tissue matrix is torn apart, allowing for efficient removal of prostate tissue. Continuous bladder irrigation is thus required to cool the tissue as well as to provide a clear aqueous medium for laser light to be transmitted to target tissue without energy loss.

The first experiments with the higher powered (80 W) KTP laser began with *ex vivo* animal models [11]. Twenty perfused porcine kidneys were used as a model for human prostate tissue. High-power KTP laser resection was compared to high-frequency current, i.e. TURP-like, resection. The 80-W KTP laser technique showed a statistically significant decrease in hemorrhage ($P < .0001$) compared to traditional TURP-like resection, demonstrating that essentially bloodless ablation of tissue could occur.

Hai and Malek presented the first human experience with 80-W KTP laser prostatectomy [12]. Ten patients were followed for 1 year after their prostatectomy in a pilot study. Patients experienced statistically significant improvements in AUA symptom score (23.2 to 2.6), quality-of-life (QoL) scores (4.3 to 0.5), Qmax (10.3 to 30.7 mL/s), and PVR (137.6 to 3 mL). The authors reported a 27% reduction in prostate volume. No patient experienced postoperative urinary retention, infection, incontinence, or erectile dysfunction; none subsequently developed bladder neck contractures or urethral stricture. Two patients in fact did not require postoperative catheterization at all. Only one patient, on active anticoagulation, experienced mild transient postoperative hematuria requiring recatheterization for 24 h. The mean operative time was 19.8 min.

Te *et al*. presented the first large, multicenter series on the use of the 80-W KTP laser in laser prostatectomy for 145 patients with long-term follow-up [13]. Of note, this experience represented the initial laser experience of this technology with these centers, testing ease of use. Significant and durable improvements in AUA symptom index (AUA SI) scores, QoL scores, Qmax, and PVR were demonstrated up to 12 months postoperatively. Mean AUA symptom scores declined from 24 to 1.8 at 12 months; mean QoL scores improved from 4.3 to 0.4, Qmax from 7.7 to 22.8 mL/s, and PVR from 114.2 to 7.2 mL. Mean prostate volume, as determined by ultrasound, decreased from 54.6 to 34.4 mL. Mean operative time was 36 min, and no patient required a blood transfusion. More than 30% of patients were sent home without a catheter; those with postoperative catheters had them removed in a mean of 14 h. Reported morbidities were generally minor; 8% of patients experienced

mild-to-moderate dysuria lasting more than 10 days, 8% had transient hematuria, and 3% had postoperative retention. Among the 56 men who were potent prior to the procedure, 27% experienced retrograde ejaculation but none of them experienced impotence.

As a novel procedure, there are growing numbers of reports of long-term outcomes of 80-W KTP laser prostatectomy. Ruszat *et al*. published the largest series of 80-W KTP laser prostatectomies. At a single center, 500 patients underwent PVP, including 45% taking oral anticoagulation. After 3 years, 26.2% of patients had follow-up and mean AUS SI, PVR, and QOL were significantly improved compared to baseline. At 60 months, the retreatment rate was 6.8% and reoperation rate was 14.8%. Urethral and bladder neck strictures were observed in 4.4% and 3.6% of patients, respectively, comparable to the rate in TURP [14]. Te *et al.* reported 3-year multicenter long-term follow-up in 139 patients who underwent 80-W KTP laser prostatectomy. At 3 years, 33.8% of patients had follow-up and improvements in symptom relief and urinary flow rate were durable [15]. The retreatment rate was 4.3%.

One of the advantages of the 80-W KTP/532-nm laser is the ability to perform laser prostatectomy on larger glands with good outcomes and an excellent safety profile. Sandhu *et al*. detailed large prostate volume resection with the 80-W KTP laser [16]. Sixty-four men with BPH and prostates with volumes of at least 60 mL (mean 101 mL) who had failed medical therapy underwent vaporization with the 80-W KTP laser. The mean operative time was 123 min. The International Prostate Symptom Score (IPSS) decreased from 18.4 to 6.7 at 12 months; Qmax increased from 7.9 to 18.9 mL/s, while PVR decreased from 189 to 109 mL. No transfusions were required nor was there evidence of postoperative hyponatremia. All 62 patients were discharged within 23 h. This was the first evidence that the 80-W KTP laser could be used as a safe and effective therapy with durable results for large volume prostatectomy.

Pfitzenmaier *et al*. conducted a comparative study between vaporization of prostates greater than or equal to 80 mL (39 of 173 patients) and those smaller than 80 mL. The authors found that PVP was safe and effective in prostates greater than or equal to 80 mL but the reoperation rate was higher. In another study, Rajbabu *et al*. assessed 54 consecutive patients with prostates of greater than 100 mL who underwent 80-W KTP laser prostatectomy. Another recent study of 150 consecutive patients with lower urinary tract symptoms who underwent laser vaporization with the 80-W KTP laser showed a decrease in storage and voiding symptoms of 81.8% and 90.9%, respectively, at 12 months [17]. Consistent with other published series, these studies further support the procedure's safety, efficacy, and durable improvements on IPSS and QoL [18].

The safety of the 80-W KTP laser prostatectomy has been studied in patients at high cardiopulmonary risk, and demonstrated to be excellent due to the excellent hemostatic profile and perioperative hemodynamic stability of the procedure. Reich *et al*. performed 80-W laser prostatectomy on 66 patients with an American Society of Anesthesiology Score of 3 or greater [19]. Of these patients, 29 were being treated with ongoing oral anticoagulation or had a severe bleeding disorder. No major complications occurred during or following the procedure and no blood transfusions were required. Two patients required reoperation within 12 months due to recurrent urinary retention. Mean improvements in IPSS (20.2 to 6.5) and peak flow (6.7 to 21.6 mL/s) were durable at 12 months.

The final safety aspect of the 80-W KTP laser to be studied in detail was its use in anticoagulated patients at high risk for clinically significant bleeding. A series of 24 anticoagulated patients with BPH were treated with laser prostatectomy using the 80-W KTP laser [20]. Of these, eight were on warfarin, two on clopidogrel, and 14 on Aspirin. Eight (33%) of these patients had had a previous myocardial infarction; seven (29%) cerebrovascular disease, and seven (29%) peripheral vascular disease. No patients developed clinically significant hematuria postoperatively and none developed clot retention. No transfusions were required and there were no thromboembolic events.. Follow-up revealed a decrease in IPSS from 18.7 to 9.5, as well as an increase in Qmax from 9.0 to 20.1 mL/s at 12 months. PVR decreased from 134 to 69 mL at 1 month but this was not statistically significant beyond that time point. In this study, all patients underwent PVP safely without any adverse thromboembolic or bleeding events. Significantly, more energy and time were required for lasing per gland size in these patients [21].

There is a growing body of literature comparing 80-W KTP laser prostatectomy to TURP. Ruszat *et al*. conducted a study in 396 patients randomized to either 80-W laser prostatectomy or TURP [22]. Interim 24-month follow-up data found the rates of intraoperative bleeding (3% vs 11%), blood transfusion (0% vs 5.5%), capsule perforations (0.4% vs 6.3%), and early postoperative clot retention (0.4% vs 3.9%) were significantly lower in the laser group. There was no significant difference in IPSS and PVR. After 12 months, size reduction was greater in the TURP group (66% vs 44%) and the rate of repeat procedure was greater in the PVP group (6.9% vs 3.9%, not significant). Bouchier-Hayes *et al*. reported data on 120 patients randomized to undergo TURP or 80-W laser PVP [23]. At 12 months equivalent improvements in IPSS and flow rates were demonstrated. Length of hospitalization, length of catheterization, and adverse events were lower in the laser group. In a nonrandomized study, Bachmann *et al*. studied 101

patients who underwent either TURP or laser prostatectomy. Perioperative morbidity and symptom improvement was equivalent in the groups at 6 months [24]. Another randomized study has yielded divergent results. In this study, 76 patients with a prostate size of greater than 70 mL were randomized to TURP and 80-W laser prostatectomy [25]. Procedure time was shorter for the TURP group. Hospitalization stay and catheterization time were significantly shorter in the laser group. There was a significant difference in favor of TURP in terms of improvement in IPSS, PVR, and Qmax, as well as volume reduction. In addition, reoperation rate was higher in the laser group. An Australian study had similar results when comparing patients randomized to either 80-W laser prostatectomy or TURP [26]. Both groups showed a significant increase in mean urinary flow rate, improvement in IPSS scores, and no difference in sexual function at 1-year follow-up.

120-W data

The 80-W KTP laser system evolved to a higher power system (HPS) capable of 80–120 W. This laser emits the same 532-nm wavelength, with the same hemostatic properties as the 80-W KTP laser [27], but utilizing a different crystal. The 532-nm 80-W KTP laser is created by passing a 1064-nm Nd:YAG laser beam through a KTP crystal. In contrast, the 120-W HPS 532-nm wavelength is created by passing a Nd:YAG laser beam through a lithium triborate (LBO) crystal. The 532-nm LBO-based system also has a beam that is better collimated than the KTP beam.

Several animal studies have been performed with the 120-W 532-nm laser. Lee *et al*. investigated the use of the 120-W laser in five male beagles [28]. PVP was performed in antegrade fashion through a suprapubic cystotomy at 40, 80 and 120 W settings for three distinct firing periods (5, 10 and 20 s) at unique locations in the prostate. The 120-W HPS consistently vaporized more tissue per unit time, while the depth of coagulation (1.2–2.5 mm) was decreased compared to the lower powered systems. Kang *et al*. compared the use of the 120-W HPS laser to the 80-W HPS laser and the 80-W KTP laser in 96 specimens of bovine prostate tissue [29]. The 120-W HPS laser vaporized bovine prostate tissue more efficiently than the 80-W KTP laser and coagulation was equivalent. Lee *et al.* advised caution with the higher power setting, especially at 120 W due to the potential higher risk of capsular perforation and bladder wall perforation. Additionally, it is observed that higher power provides more efficient vaporization with less hemostasis, and as a result, utilization of the lower power coagulation setting is important in achieving hemostasis.

Heinrich *et al*. used blood-perfused porcine kidneys to determine the ablation capacity, hemostatic properties, and coagulation depth of a 120-W 532-nm laser compared to an 80 W laser [30]. The 120-W LBO laser offered a significantly higher tissue ablation capacity compared with the conventional 80 W KTP laser. The increased efficacy of the 120 W laser device was accompanied by a higher bleeding rate and a slightly deeper coagulation zone.

Few studies have been published on the safety and efficacy of the 120 W 532 nm laser prostatectomy in humans [31]. In a multicenter prospective study, 305 patients with BPH underwent laser prostatectomy with the 120 W HPS laser. Increases in maximum flow rate (Qmax) and decreases in postvoid residual urine, International Prostate Symptom Score, and prostate volume from baseline to follow-up were significant ($P < .001$) in all patients. A subgroup analysis was done in three groups of patients: those in retention (n = 63), on anticoagulation (n = 67), and with prostates ≥ 80 mL (n = 52). Complications were comparatively low in all groups.

In another study by Al-Ansari *et al*. randomized 120 patients with BPH to TURP or 120 W 532 nm laser [32]. A total of 55 and 54 patients completed 36 months of follow-up in the TURP and 532-nm laser groups, respectively. Baseline characteristics were comparable. Mean operative time was significantly shorter for TURP. Compared to preoperative values, there was significant reduction in hemoglobin and serum sodium levels at the end of TURP only. In the PVP, no major intraoperative complications were recorded and none of the patients required blood transfusion. Among TURP patients, 12 (20%) required transfusion, three (5%) developed TUR syndrome, and capsule perforation was observed in 10 patients. There was dramatic improvement in Qmax, IPSS, and PVP compared with preoperative values and the degree of improvement was comparable in both groups at all time points of follow-up. Storage bladder symptoms were significantly higher in PVP. A redo procedure was required in one TURP patient and six PVP patients ($P < .05$). Two TURP patients and four PVP patients developed bladder neck contracture ($P > .05$), treated by bladder neck incision; none in either group experienced urethral stricture or urinary incontinence.

Future of the 532-nm laser

The most recent advance is the Food and Drug Administration (FDA) approval of a 532-nm LBO-based laser system, capable of 180 W, with a feedback mechanism to control energy exiting the fiber (GreenLight XPS™; American Medical Systems, Minnetonka, MI, USA) system and a new water-cooled redesign high-

power fiber (MoXy™ Fiber; American Medical Systems). The modifications in this system innovatively increase the safety and efficacy of this laser prostatectomy.

One aspect that predisposes a fiber to degradation, resulting in less collimation and deflection of the laser pathway, is heating at the tip of the fiber, probably caused by contact with tissue or adherence of tissue to the tip acting as a heat sink. The infrared-based feedback mechanism provides an automatic safety system; it monitors the heat generated at the fiber tip and if overheating is detected, which could cause fiber damage or failure, it briefly disables the beam to allow cooling and maintenance of a safe temperature. The system detects the infrared light emitted by all heated bodies to determine the temperature of the tip of the fiber. If excessive temperatures are reached, i.e. the fiber tip is embedded with excessive tissue contact, or excessive adherent tissue, or prostatic stones are encountered, etc., the laser emission is stopped momentarily. This will continue to occur as long as the source of the excessive heat is present.

Another new modification is applied to the coagulation power mode. The new 180-W capable system delivers the lower power coagulation mode laser light in intermittent pulses. This intermittent laser pulse modality mimics the intermittent delivery of power in electrocautery coagulation for hemostasis. However, the more important utility is the ability to better utilize the fiber for contact coagulation of arterial bleeders. With intermittent pulses, laser coagulation heat on tissue contact is limited by the intermittent pulsing and continuous flow of room temperature irrigant over the tip.

Finally, to improve the rate of vaporization efficiency, the power of the 180-W capable system was increased. The original 120-W system was rated at 120 W and the new system has a maximal power output of 180 W. To allow utilization of the 180-W capable system, while maintaining the same power density characteristic of the 120-W system and its fiber, a new fiber design was necessary. This new fiber has a wider diameter (750 μm vs 600 μm), which provides a wider and more efficient tissue vaporization effect.. This increase in fiber diameter of 0.15 mm increases the beam area by 50%. In addition, the end cap of the fiber has been redesigned to limit stray beams during the procedure. Most importantly, the cap is actively cooled with by room temperature normal saline flowing through the fiber at 1 mL/s and exiting at the beam point. This cooling feature also helps to protect the fiber from degradation, and only minimally reduces the amount of light delivered to tissue over the course of a long laser procedure.

All these modifications reduce fiber devitrification, the process by which the glass at the tip of the fiber becomes opaque, which then leads to power degradation during the procedure. Additionally, the continuous aqueous flow, metal cap, and feedback feature limit the build up of coagulated tissue on the tip of the fiber, which is one of the main causes of fiber failures. With these features, one fiber may be all that is needed for the treatment of most large prostates.

In our experience, we have found the 180-W laser with the actively cooled fiber to be extremely efficient. With the standard nonaqueous cooled fibers at 120 W, consistent efficiency is obtained to about 150 000 J. With the new aqueous cooled fibers and the 180-W laser system, power to 180 W can be utilized. However, at 120 W or greater, higher efficiency is obtained at the expense of hemostasis during the case. Especially at settings above 120 W, there is rapid vaporization of tissue while coagulation is decreased. This increased power and efficiency leads to a concern that if there were a misfire within the bladder at settings such as 180 W, damage to the bladder, including perforation, ureteral orifices, etc., could occur very quickly and without recognition by the surgeon. The actively cooled fiber predisposes to a reduction in the number of mechanical failures and in most cases only one fiber was required during treatment.

Patient preparation

There is minimal patient preparation prior to laser prostatectomy. Many patients today are routinely taking Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and other medications that may affect platelet function. Others may be actively receiving chronic anticoagulation with agents such as coumadin. Although these patients may have raised concerns in the era of electrocautery TURP, the hemostasis associated with laser prostatectomy allows select patients to be treated without stopping or changing their medical regimen [20, 33, 34] . However, the risks of treatment on active anticoagulation therapy should be clearly stated to the patient, as the risk of bleeding will always be higher while on anticogulation medication than off it.

Age-appropriate patients should be screened with both digital rectal examination (DRE) and serum prostate-specific antigen (PSA) levels. Prostatic abnormalities may be evaluated with transrectal ultrasound and biopsy as indicated. Such screening is important in laser prostatectomy since pathology is not adequately sampled for histologic examination [35].

A minority of patients with bladder outlet obstruction due to BPH will present with active urinary tract infection or significant pyuria. This should be treated prior to laser prostatectomy, especially since potential coagulated, nonperfused, necrotic tissue can remain *in situ* postoperatively and may become seeded with bacteria in the presence of active infection. For the typical patient

who presents with sterile urine, routine antibiotic prophylaxis is recommended prior to laser resection of the prostate.

The consent for laser prostatectomy is very similar to that obtained for other transurethral operations. Patients are informed that they will require an anesthetic, and of potential complications associated with any invasive urologic procedure, such as bleeding, urinary tract perforation, infection, urinary incontinence, erectile dysfunction, retrograde ejaculation, and urethral stricture or bladder neck contracture. Finally, the patient should be informed that remaining tissue can grow back, causing recurrent voiding symptoms, and that additional prostate surgery may be required.

Preoperative preparation

There is no special preparation for a laser prostatectomy. Standard patient positioning in the dorsal lithotomy position with sterile draping and cleansing preparation is used, as for routine cystoscopy or any other transurethral operation. A properly functioning laser source and compatible laser delivery fiber are required.

Laser safety should be of paramount importance in the operating room. Laser energy can cause significant thermal injury to human tissues, including irreversible retinal damage. All operating room personnel and the patient must wear proper eye protection. Operating room windows should be covered to prevent the inadvertent passage of stray laser light; doors should be appropriately marked to warn outside personnel that laser energy is in use. When the laser is not being actively used, and in particular when the fiber is removed from the cystoscope and the working end lies free on the operative field, the surgeon should remove their foot from over the laser pedal and nursing personnel should close the shutter on the laser machine to prevent accidental firing. Paper drapes can be easily ignited and patients burned with the beam.

Technique

Laser prostatectomy requires local, regional or systemic anesthesia due to the pain associated with acute laser burns to the prostatic urethra. Leach *et al*. have in addition described a transperineal injection technique using lidocaine and bupivacaine to achieve local prostatic and pudendal nerve blockade, which when combined with intravenous sedation may also provide adequate anesthesia to perform laser prostatectomy [36]. When utilizing injection anesthetic, it is important to be aware of the maximum dosage as overdosing may result in significant adverse events.

Cystourethroscopy is performed with a standard 21–26F cystoscope. However, laser prostatectomy requires the specialized continuous-flow cystoscopes that have been purpose designed for laser prostatectomy. If continuous flow irrigation is inadequate to provide a clear field of vision, a suprapubic catheter can be placed to provide continuous intraoperative irrigation flow as well as postoperative urinary drainage. Since clinically negligible fluid absorption occurs during laser prostatectomy, special irrigation solutions are not required; normal saline is relatively inexpensive, is the fluid of choice compared to osmolar solutions, and provides good visualization. Room temperature, as opposed to warmed, irrigation provides cooling for the laser delivery fiber, limiting thermal damage as well as prolonging the usable lifespan of fibers (see above). The irrigant is hung 30 cm above the bladder and allowed to flow under gravity. Suction irrigation to the outflow port should be avoided, as it is unnecessary and may increase the risk of inadvertent bladder perforation. The prostatic anatomy is carefully assessed and the prostatic urethral length from the bladder neck to the proximal aspect of the verumontanum is inspected. The laser fiber is then passed through the working port of the cystoscope and visualized in the prostatic urethra in preparation for beginning laser application.

Laser energy is directed at the locations along the prostatic urethra that are obstructed, such as medial, lateral and anterior lobe tissue. A systematic and aggressive approach to laser prostatectomy will ensure complete laser treatment of all obstructive tissue elements. Laser resection may begin with either the medial or lateral lobes, but should always begin proximally and continued distally, working away from the bladder neck and toward the verumontanum: after the proximal prostate near the bladder neck is opened by superficial tissue vaporization, there will be improved irrigation flow for the more distal laser treatment.

Laser energy may be applied in a continuous fashion over an area, barring excessive tissue resection (e.g. perforation). PVP, the technique described for 532-nm laser prostatectomy, is often described as "painting" systematically over the surface of the prostate until a TURP-like cavity is formed. However, a more correct description is "mowing the lawn," since a systematic sweeping technique is utilized to remove tissue in layers. Additionally, the optimal distance from tissue is small, within one fiber cap in a noncontact technique. Excellent vaporization results in a stream of bubbles, which represent the steaming away or vaporization of tissue. The laser source is used first to vaporize the median lobe to the level of the trigone. Once a channel has been created that allows adequate irrigation, the lateral lobes are next vaporized. This is followed by apical vaporization. At the end of the PVP procedure, a cavity should be present where the adenoma once was. If

bleeding is encountered during PVP, the laser setting is lowered to allow coagulation instead of vaporization and the target area is coagulated. Optimally, the fiber tip should be held just off the mucosal surface such that a clear plane of water stands between the tip and tissue; by moving the beak of the cystoscope close to the fiber tip, the scope can be used to hold tissue away from the tip in many instances. In addition, resecting proximal before distal prostate tissue aids in freeing tissue from the fiber. Finally, when all else fails and occlusive prostate tissue must remain in contact with the metal mirror during treatment, a very slight vibratory motion of the fiber tip, i.e. no more than 1–2 mm longitudinal oscillation, combined with good water flow can keep tissue from adhering to the metal fiber tip. For all fibers with a mirror reflecting mechanism, routine cleaning of the fiber is recommended. The build up of spattered particulate on the fiber surface during treatment can cause superheating with fiber degradation. Prophylactic cleaning between each laser application and ensuring adequate room temperature water flow throughout the duration of each individual laser application are the most important means of preserving fiber integrity.

Advanced technique

Once the basic technique is mastered, the 532-nm laser can be used to enucleate, vaporize, and resect tissue. This technique is referred to transurethral laser enucleation of the prostate (TLEP). The procedure allows pathology to be collected and analyzed, improves surgical debulking of obstructive prostate tissue, and increases tissue removal efficiency, shortening operative times. This advanced technique is essentially a hybrid between TURP and laser vaporization utilizing the 532-nm laser. The technique can be quickly learned by those with prior transurethral resection skills. However, there is a learning curve to transurethral navigation of complicated and long anatomy that is clearly related to experience of transurethral resection anatomy. Pathology is provided and resection/enucleation is very complete. An incision is made through the median lobe until the bladder neck fibers can be seen (Figure 128.1). Sweeping motions with the side-fire laser fiber ensure that a wide channel is made, which allows for strong flow of cooling irrigant. Incisions are made lateral to the median lobe while visualizing ureteral orifices to ensure their safety. The intervening tissue between the incisions is divided into smaller chips. Multiple vaporization–enucleation–incision cycles are made down to the fibers of the prostatic capsule. Intervening tissue is vaporized, incised, and pushed into the bladder. Apical tissue proximal to the verumontanum is carefully ablated with care to preserve the verumontanum.

Postoperative care

At the conclusion of laser prostatectomy, a urinary catheter is left in place to provide drainage. A suprapubic catheter may be left in place to facilitate early or repeated voiding trials if desired.

Many routinely discharge patients following complete recovery from anesthesia, making laser prostatectomy essentially an outpatient procedure. Catheter drainage to a urinary leg bag if necessary can be maintained and easily mastered by most patients. Patients should note that if they have a history of preoperative urinary retention or detrusor hypocontractility with a large preoperative residual urine volume, they may require longer catheterization times. Postoperative management with suprapubic catheter drainage in these individuals may be ideal to allow easy or repeated voiding trials if needed.

Following catheter removal, immediate improvement in voiding may not occur. This may be due to inefficient vaporization resulting in a greater degree of coagulation necrosis. In fact, patients may have little or no change in voiding during the first 1–2 weeks postoperatively and they may experience slightly worse symptoms while the treated prostatic transition zone sloughs. During this time, patients may note a cloudy, white appearance in the urine, caused by proteinaceous material from the dissolving prostate; others may note the passage of minute particulate matter in the urine. This phase of active tissue dissolution can be associated with symptoms of mild dysuria, which are usually relieved by NSAIDs as needed. Phenazopyridine (Pyridium) appears to be much less effective for this syndrome, but may also be used as needed. By 4–6 weeks following laser prostatectomy, most patients begin to note a significant improvement in their voiding pattern. Improvement will continue in most men for an additional 6–12 weeks and longer, until maximum voiding outcome is achieved. By 3 months, voiding outcomes are similar to those expected after electrocautery TURP. With the more efficient vaporization and limited coagulation necrosis with high-power 532-nm laser applications, improvement may occur as short as a few days to a week with minimal dysuria.

Because of the superior surgical hemostasis associated with laser prostatectomy, significant restrictions on physical activity are not as limiting, even in the immediate postoperative period. After catheter removal, sexual intercourse is allowed immediately if desired but recommended at about 1-month postoperatively. Patients should be warned of the possibility that the ejaculate may be temporarily dark or bloody. The most significant risk from activity is hematuria, which is usually clinically insignificant but can on occasion result in clot

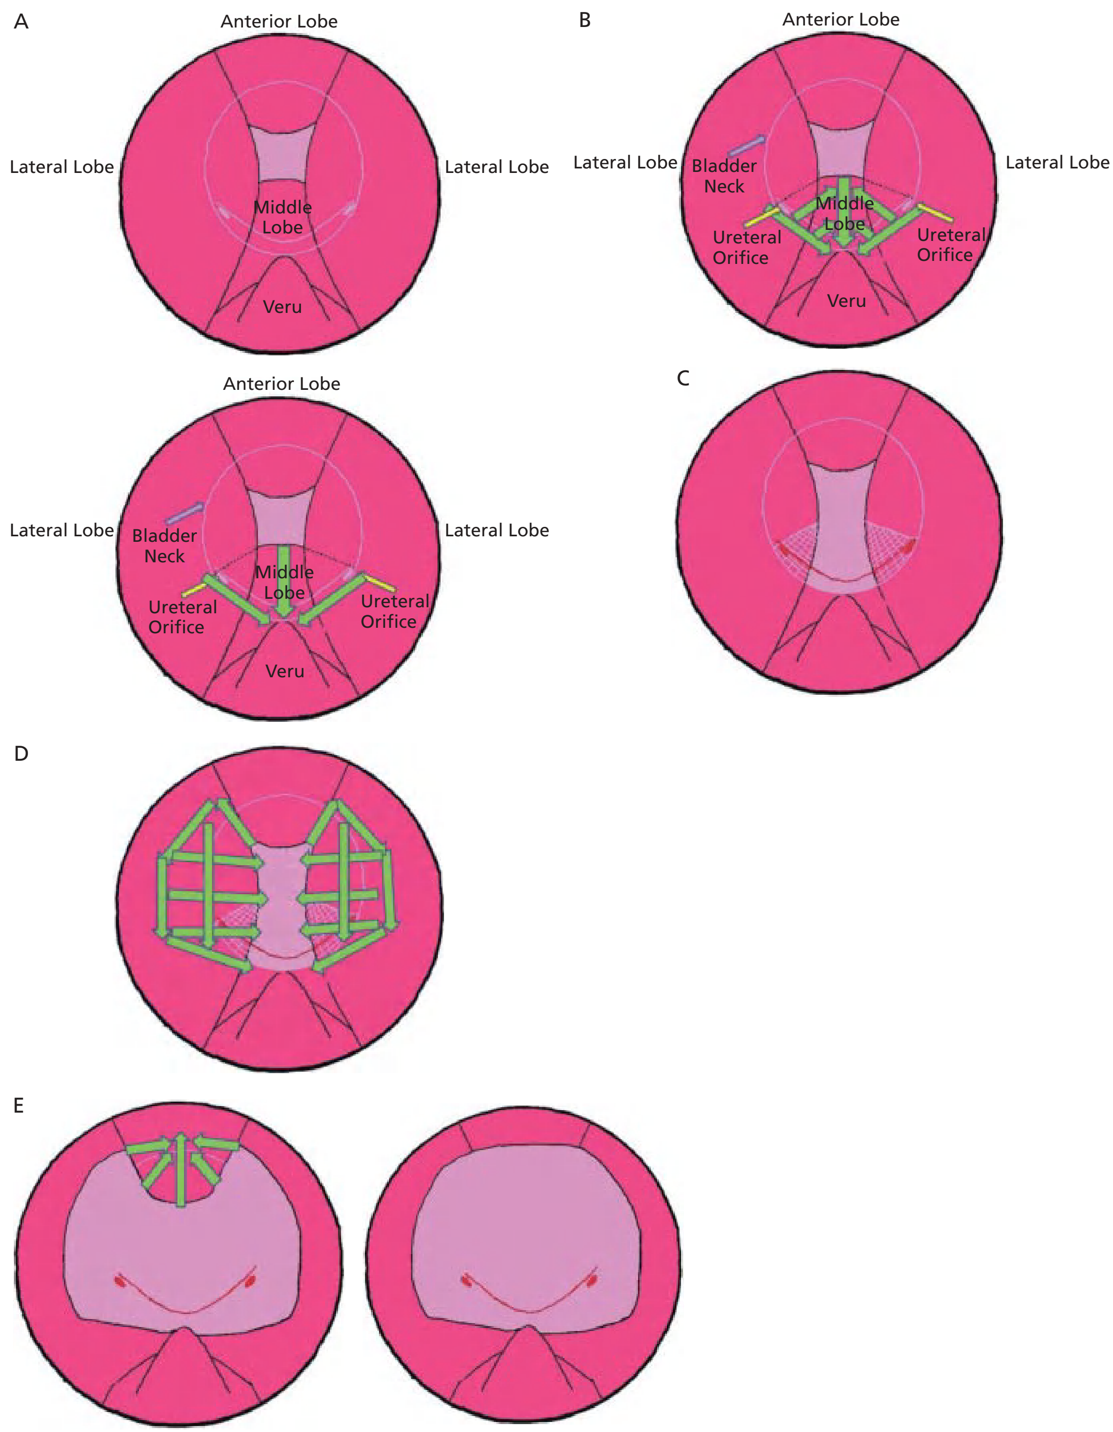

Figure 128.1 Transurethral laser enucleation/vaporization technique as viewed through the cytoscope. (A) A wide incision is made through the median lobe until the bladder neck fibers can be seen. This channel should be wide enough to ensure a strong flow of cooling irrigant. Then, incisions are made lateral to the median lobe. It is important to visualize the ureteric orifices. (B) The intervening tissue between the incisions, if large, is divided into smaller chips. The chips are vaporized to reduce bulk before they are incised and placed into the bladder. (C) The median lobe is removed in this manner on both sides to view the ureteral orifices clearly from behind the bladder neck. (D) Multiple cycles of vaporization–enucleation–incisions are made, starting at the 11 o'clock position of the lateral lobe down to the fibers of the prostatic capsule. The 11 o'clock incision is continued medial to join the median lobe defect at the 7 o'clock position. Intervening tissue is vaporized, incised, and pushed into the bladder. The same procedure is done to the other side to remove the contralateral lateral lobe, starting at the 1 o'clock position to the 5 o'clock position. Apical tissue proximal to the verumontanum is carefully ablated with care to preserve the verumontanum. (E) Anterior tissue at the 12 o'clock position is then incised–vaporized–enucleated as needed to connect the 1 o'clock position to the 11 o'clock position. The goal is to achieve a transurethral resection (TURP)-like cavity with removal of tissue to the capsule and with a view of the ureteral orifice, as well as removal of any intravesical components. After resection is completed, the tissue chips are irrigated out with a combination of transurethral evacuators and graspers. With careful lasering of tissue to small chips, use of a morcellator is unnecessary.

retention requiring transient catheterization and irrigation.

Serum levels of PSA rise approximately 10-fold following laser prostatectomy, generally peaking on the first postoperative day [37, 38]. This seemingly corresponds with the height of capillary leakage and tissue edema after the laser burn injury. By 3 months, we have observed serum PSA levels to be at or below baseline in more than half of our patients. Approximately 90% have returned to or are below baseline values by 6 months. Those with significant and persistent elevations of PSA levels beyond this time probably should be evaluated for subclinical prostatic infection or occult carcinoma.

Complications

All reported studies have noted markedly less morbidity associated with laser prostatectomy compared with traditional surgical approaches. Bleeding is the main complication of traditional electrocautery TURP, often necessitating transfusion and causing associated problems such as clot retention, premature termination of the procedure, and inadequate relief of obstruction [39]. Bleeding can also result in continuous catheter irrigation and complications, such as stricture secondary to traction on the Foley catheter. Rarely, uncontrolled bleeding can even require open packing of the prostatic fossa. Poor visibility because of bleeding is also thought to be a cause of sphincteric damage and incontinence resulting from TURP. The incidence of hemorrhage requiring blood transfusion is 3.9% and this increases twofold if the amount of resected tissue exceeds 45 mL or if the resection time is longer than 90 min. In contrast to TURP, which cuts across the prostatic parenchyma and opens prostatic venous sinuses, laser prostatectomy seals blood vessels as it coagulates the transition zone and prevents both absorption of irrigating fluid and hemorrhage; the hemostasis associated with laser prostatectomy is thus superior, with even multiple studies of anticoagulated patients undergoing resection without bleeding complications [20, 40, 41].

Irrigant fluid absorption during electrocautery TURP results in a 2% incidence of TUR syndrome because of dilutional hyponatremia, glycine-induced ammonia intoxication or the direct toxic effect of glycine [39]. As with bleeding, fluid absorption increases with larger glands and longer resection times. Laser prostatectomy minimizes this complication, again through its sealing zone of coagulative effect on tissue which prevents fluid absorption.

The incidence of urethral stricture after electrocautery TURP is 3.1%; if bladder neck contractures are included, this figure approaches 5% [39]. Stricture formation is thought to be secondary to trauma induced by the large size of the resectoscope as well as the use of low-intensity, coagulating current, which penetrates deeper into tissue than cutting currents. Since laser procedures do not use electrical current, the cystoscopes utilized are smaller in size, and the overall operative time is usually shorter, the incidence of stricture is lower [42, 43]. The incidence of reoperation for residual obstructive tissue is difficult to determine since most published series of laser prostatectomy have documented initial experiences only with this technology. Our experience is that the incidence of strictures and bladder neck contracture is higher in patients with bladder dysfunction or bladder diverticulum, or following long procedures utilizing larger diameter scopes [44].

Postoperative infections may also occur after TURP. The incidence of urinary tract infection following TURP is 15.5% (median) while epididymitis occurs in 1.2% [39]. Urinary tract infections have been reported in 1–20% of patients following laser prostatectomy and epididymitis in 5–7% of patients [45–50] . The treatment of such infections may be more problematic in laser prostatectomies secondary to the residual necrotic prostate tissue that remains *in situ* for several weeks after laser coagulation. When this occurs, the most common manifestation is subacute prostatitis, characterized by significant and persistent irritative voiding symptoms, with mild prostatic and/or epididymal tenderness on examination, persistent pyuria, and positive urine cultures. Two cases of frank urosepsis have been reported following laser prostatectomy, both requiring TURP to remove infected necrotic prostate tissue [51]. Aggressive antibiotic therapy is therefore warranted in these patients.

Finally, retrograde ejaculation represents another potential side effect of electrocautery TURP, occurring in up to 90% of patients. Data with the 80-W KTP laser show that retrograde ejaculation also represents a potential problem in laser prostatectomy, with a 27% incidence of retrograde ejaculation [13]. The incidence of impotence following electrocautery TURP ranges from 4% to 13% [39], while its overall incidence following all forms of laser prostatectomy is rare. While data are limited, available 80-W KTP data show no loss of potency in patients treated with laser prostatectomy [13].

Contraindications

There are scenarios when laser coagulation of the prostate is not indicated, and where electrocautery resection may still be advantageous. These include certain cases of bladder cancer, in which acute electrocautery resection of the bladder neck or enlarged prostate may be necessary to access tumors behind the bladder neck, especially anteriorly. Rarely, this maneuver may also be needed for ureteroscopic access. In cases in which histologic assessment of the prostate for invasion by

transitional cell carcinoma is required for staging of malignancy, electrocautery resection is indicated. Finally, in the uncommon case of chronic, recurring prostatitis where electroresection of the prostate may be used to remove infected tissue and/or prostatic calculi, laser prostatectomy cannot substitute for an aggressively performed TURP. In the rare case of a prostatic abscess that must be unroofed transurethrally, electrocautery resection is similarly indicated.

Conclusions

Laser prostatectomy has proved to be a safe and efficacious surgical intervention to relieve symptomatic bladder outlet obstruction. Overall morbidity contrasts favorably with standard surgical approaches. Moreover, laser technology is generally accessible to the practicing urologist. The transurethral endoscopic approach and operative techniques are not complex. These attributes have positioned laser prostatectomy as an accepted and often preferred surgical treatment of BPH.

CHAPTER 129
Thulium Lasers

Andreas J. Gross
Department of Urology, Asklepios Klinik Barmbek, Hamburg, Germany

Introduction

A good understanding of laser principles is required to choose the appropriate laser for any medical application [1, 2]. Important in this respect is the optimization of the absorption process of light in tissue, as laser radiation is simply directed light of a narrow bandwidth. This is synonymous with a single color and applies for all regions of the invisible and visible electromagnetic spectrum.

For surgical applications the most important process in the interaction of light and tissue interaction is absorption. When the laser beam hits tissue, a certain percentage is reflected by the boundary layer. The reflected radiation not only is lost for the surgical purpose but this laser energy, in the form of heat, may be a risk to surrounding tissue. Reflection depends on the optical properties of the tissue and the irrigant surrounding it, but is not very dependent on wavelength and therefore may be neglected when evaluating a laser wavelength for a surgical purpose. Since tissue is not homogenous, part of the incident laser beam is scattered, taking the applied laser beam out of its intended direction. The degree of scattering depends on the size of the particles that the laser beam encounters and on the wavelength of the laser. Shorter wavelengths are scattered to a much higher degree than longer wavelengths. Blue laser radiation is scattered more than green, green more than red, and red more than infrared. This scattered fraction of laser energy is not only lost for the intended purpose but may also cause unintended side effects.

In order to achieve absorption, a chromophore is required. Useful body chromophores for surgical procedures are melanin, blood, and water, although melanin has no use in urologic applications. The wavelength dependency of their absorption length is shown in Figure 129.1. The absorption length defines the optical pathway along which 63% of the incident laser energy is absorbed. Another concept, the extinction length, defines the depth at which 90% of the incident laser beam will have been absorbed and converted into heat.

With knowledge of the absorption process, it is easier to understand the laser–tissue interaction, both intended and unintended. When entering into an absorbing medium, the intensity of any laser beam decreases exponentially (Lambert–Beer's law). Absorbed laser energy is converted into heat and causes an increase in temperature. Depending on the density of absorbed heat, the impact on tissue may vary between coagulation and vaporization. The temperature in tissue increases with the density of heat per volume of tissue. This offers the opportunity for various surgical procedures, such as pure vaporization, vaporesection (in continuous wave lasers), or vapoenucleation when used for the treatment of benign prostatic hyperplasia (BPH).

The tissue effect is determined by the density of the absorbed laser power. The higher the absorption by a tissue is, the less heat is generated in its deeper layers. The understanding of this principle is important for any surgical laser application. At the same power level, a laser wavelength with a long absorption length may create a deep necrosis, whereas with a laser wavelength with a much shorter absorption length the absorbed laser power will be confined to a smaller volume which may lead to an increase of temperature above boiling

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

point and to immediate vaporization of tissue. The thulium (Tm):YAG lasers operate at a wavelength of 2013 nm and at this wavelength the absorption length is approximately 250 μm.

Pulsed and continuous wave lasers

Lasers can be divided in two major groups, pulsed lasers and continuous wave (cw) lasers. Holmium lasers are normally excited by flash lamps, which restricts the repetition rate due to heat accumulation in the laser crystal, whereas Tm:YAG lasers may operate in a cw-mode if excited by a laser diode. Pulsed holmium lasers create large pulsating steam bubbles in the irrigant surrounding the tip of the laser fiber, whereas those bubbles are much smaller for cw-mode lasers (Figure 129.2). For the holmium laser, the lifetime of a steam bubble corresponds to the duration of the laser pulse (~500 μs), which is too short to be visible in video transmission during endoscopic procedures.

The expanding steam bubble is used in holmium laser enucleation of the prostate (HoLEP) for the separation of the adenoma from the peripheral zone (see Chapter 127). Coagulation is achieved by the heat within the steam bubble. In contrast, the Tm:YAG laser constantly supports a steam bubble between the fiber tip and tissue. This bubble provides the optical contact for the laser radiation into the tissue. With fiber movement, precise cutting can be achieved. Due to its cw-mode and the absence of pulsating steam bubbles, cw Tm:YAG lasers allow smoother incisions in soft tissue, which is considered to be advantageous in urologic surgery.

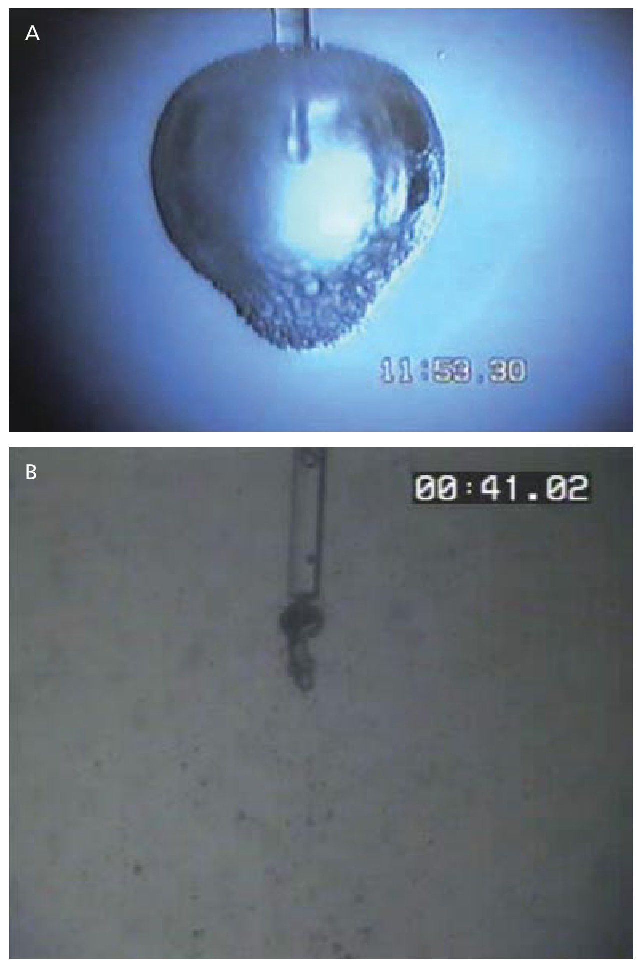

Figure 129.2 (A) Large steam bubbles in a pulsed laser (holmium laser; 2 J, 32 W). (B) Small steam bubbles in a continuous wave laser (2 μm, 50 W).

Accuracy, energy efficiency, and minimal collateral damage are all found with the cw-mode as opposed to the pulsed mode of the holmium laser.

However, the cw-mode is disadvantageous for the Tm:YAG laser's applicability for lithotripsy, since the required pulse peak mode for lithotripsy is not available in the cw mode of this laser [3].

Animal studies with thulium lasers

The first animal studies in the field of urology with Tm:YAG lasers were published in 2003. Theisen *et al.* demonstrated the tissue cutting ability of a Tm:YAG laser on pig liver, with coagulation zones of 0.8 mm or less [4]. El-Sherif and King tested the ablation abilities of thulium fiber lasers on various soft tissues *in vitro*, such as muscle, cartilage, and liver [5].

Fried reports on the vaporization of canine prostates *ex vivo* [6]. He used 88.5 ± 2.3 W of a 110-W high-power laser at a wavelength of 1.91 μm. Thus, his results may not be absolutely comparable with the commonly used Tm:YAG lasers working at 2013 nm, since absorption coefficient and penetration depth depend on wavelength and even small changes may have a relevant impact (see Figure 129.1). With the setting used by Fried, the laser works in both a cw and a chopped mode. The focus of his interest was measurement of the rate of tissue vaporization in a given time. This was 0.83 ± 0.11 g/min at 88.5-W laser power.

Thulium laser settings at 26 W, however, were not powerful enough to make efficient and accurate incision [7, 8]. The zone of thermal damage had a wide variance of 500–2000 μm. Fried stated that a higher power laser could be used to deliver more energy during a shorter pulse duration, with the intention to reduce the collateral tissue damage. Fried confirmed his original data in further *ex vivo* studies in canine prostates, and animal ureters and bladder neck tissue. He was not concerned about unacceptable collateral tissue damage, which was documented to be several hundred microns of thermally damaged tissue [7].

Whereas the first *ex vivo* studies were with soft tissue, Fried also published data on urinary stone fragmentation [9]. A cw high-power thulium fiber laser operating at a wavelength of 1.94 μm was modulated to operate in a pulsed mode with an output pulse energy of 1 J, 20-ms pulse duration, and repetition rate of 10 Hz. The fragmentation time to reduce various stones into particles of less than 2 mm was measured. In principle, high-power cw thulium fiber laser, when operated in pulsed mode, could fragment both soft and hard urinary stones, not accounting for the time this took.

Clinical experience with thulium laser treatment of the prostate

Clinically, thulium lasers were studied first in otolaryngology, pneumology, gynecology, gastroenterology, and neurosurgery [10–12]. An early paper in the field of urology dealing with the low-power vaporesection of BPH using a 50-W Tm:YAG laser was published in 2005 by Xia *et al.* [13]. Subsequently, laser treatment of the prostate has evolved as the main field for application of thulium lasers (Figure 129.3).

Vaporesection

Xia *et al.* reported on 30 patients resected using the so-called tangerine technique [13]. They sliced the prostate in tangerine-like pieces *in situ* and extracted these mechanically. This ability to cut was an important difference from the previously introduced lasers, especially the holmium:YAG (Ho:YAG) laser, which cannot cut or resect. Besides this, the application and surgical techniques of Tm:YAG lasers are very similar to those of the Ho:YAG lasers.

The 30 patients described in this first paper had a mean prostate volume of 58 mL, an average International Prostate Symptom Score (IPSS) of 19, and an average maximum urinary flow rate (Qmax) of 8.0 mL/s. The power used was 50 W. With a mean operating time of 56 min, tissue was removed at an average of around 1 g/min. This is in the range of Ho:YAG lasers, which enucleate at a rate of up to 0.71 g/min [14]. In Xia *et al.*'s first series, no significant bleeding was found during operation. No postoperative bladder irrigation was necessary. The Foley catheter remained *in situ* for 1–3 days. Blood samples before, directly after, as well as 1 and 3 months after the procedure did not reveal any changes. Three months after the operation, Qmax was 24.7 mL/s and IPSS 7.1. No cases of new onset of impotence were found. These data were confirmed at 1-year follow-up [15].

In 2007 Bach *et al.* reported their initial results for 54 patients after 70-W high-power vaporesection of the prostate (mean volume 30.3 mL) with the Tm:YAG laser and 1-year follow-up [16]. At that time, laser enucleation of the prostate with this laser had already been described [17], and a noted disadvantage of this procedure was the difficulty in removing the tissue from the bladder. Either a morcellator could be used or the so-called mushroom technique used [18]. In the latter, the prostate is left attached by a pedicle at the bladder neck and the tissue resected with a mono- or bipolar loop. Vaporesection is a protocol where small chips are produced with a Tm:YAG laser and washed out, similarly to the standard resection technique. In Bach *et al.*'s patients, Qmax was 8.1 mL/s, after exclusion of 14 patients with an acute

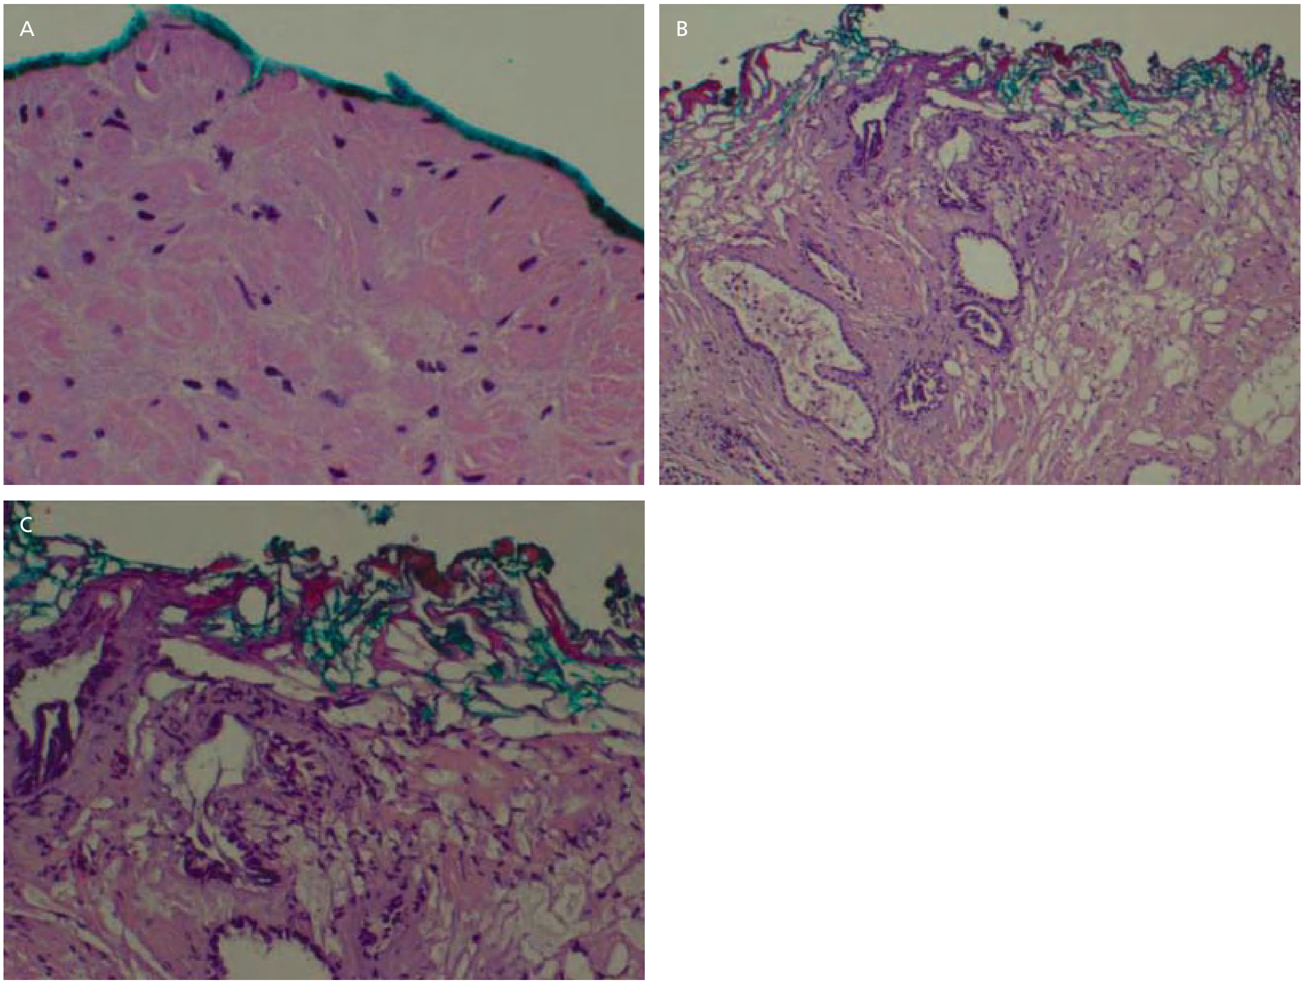

Figure 129.3 Human prostate following treatment with a 70-W, 365-μm fiber, thulium laser in contact mode. (A) Magnification ×20; (B) ×40; (C) ×100.

urinary retention. In these first results, removal of 0.6 g/min was achieved, which increased with experience to 1.5 g/min. Mean catheter time was 1.7 days (1–3 days). Transfusion was not required in any patient. However, six patients showed urinary tract infection with irritative voiding symptoms 1–2 weeks postoperatively, which required antibiotic therapy. After 1 year, no bladder neck stricture or urethral stenosis had occurred. These results were confirmed in the 18-months follow-up of the same group of patients [19].

After these reports from clinical practice, a systematic *ex vivo* evaluation of the thulium laser was performed by Wendt-Nordahl *et al.* [20]. The ablation capacity as well as the hemostatic properties were tested at different power settings in a previously used model of the isolated blood-perfused porcine kidney. Histologic examination of the ablated tissue followed. These results were compared to transurethral resection of the prostate (TURP) and treatment with the 80-W KTP laser. At a power setting of 70 W, the thulium laser displayed a higher tissue ablation rate, of an average of 6.56 g in 10 min. This is of course far more than achieved in clinical practice, since no time is lost for surgical orientation. The KTP laser ablated of 3.99 g of tissue in the same time, whereas with TURP 8.28 g was removed in 30 s. The bleeding rates were 0.16, 0.21, and 20.14 g/min, respectively. The corresponding depths of the coagulation zones were 264, 666.9, and 287 μm, respectively. In conclusion, this study shows that the thulium laser offers a higher tissue ablation capacity and similar hemostatic properties to those of the KTP laser, and in comparison to TURP the bleeding rate was significantly reduced. The smaller quantity of removed tissue as compared to TURP reflects the fact that the thulium laser was used for vaporization only.

The first randomized prospective study was performed by Xia *et al.* [21]. They compared the thulium laser and TURP in clinical practice. Xia *et al.* randomized 100 patients into two groups: 52 underwent laser resection using the tangerine technique mentioned above,

and 48 standard TURP. Preoperative assessment included IPSS, International Index of Erectile Function (IIEF), and urodynamic studies. Those parameters were re-evaluated at 1, 6, and 12 months. Catheterization time was significantly shorter in the laser group (45.7 vs 84 h; $P < .0001$). Blood loss was less in the laser group with a decrease in hemoglobin of 0.92 g/mL vs 1.46 g/mL ($P < .001$) in the TURP group. IPSS and IIEF as well as urodynamic studies did not reveal any significant difference between the groups. Both groups benefitted from the respective interventions.

Results from a larger series of patients (n = 200), also with larger prostate sizes (up to 120 g), were published by Mattioli *et al.* [22]. They used a 70-W laser with both bare-ended and side-firing laser fibers. Bare-ended fibers used with the cw thulium laser are applicable for all BPH protocols, such as vaporization, vaporesection, and vapoenucleation; however, side-firing fibers are used for vaporization only. Mattioli *et al*. advocated the use of both fibers They used a laser that enabled switching with a foot pedal between the two modes, and preferred to resect first and vaporize thereafter. In patients with prostates smaller than 35 g, vaporization was performed; in those with prostates larger than 35 g vaporesection and/or vaporization was performed. Mean catheterization time was 16 h (range 12–72 h). The efficacy of the procedures was evaluated with uroflowmetry, postvoid residual volume (PVR), and evaluation of the symptoms with the IPSS questionnaire. The authors concluded that the clinical outcome was comparable with TURP and the KTP and Ho:YAG lasers.

Szlauer *et al.* have published a DVD on the vaporesection procedure with a thulium laser [23]. This shows the main steps of the technique as introduced by Bach *et al.* [16]. The laser fiber is moved semi-circumferentially from the verumontanum towards the bladder neck, thereby undermining tissue and cutting chips. Szlauer *et al.* reported on the evaluation of 56 nonconsecutive patients. The mean procedure time was 60 min, postoperative irrigation was necessary in 19 of 56 patients (29%), and the mean time of catheterization was 23 h. The decrease of hemoglobin was low at 0.2 mg/mL until the day of discharge. Average Qmax improved from 8.1 to 19.3 mL/s ($P < .001$), and the PVR decreased from 152 to 57 mL ($P < 0.05$). This study included the first report of the need for blood transfusion (2 patients, 3.6%) after thulium laser procedures. Two patients needed recatheterization postoperatively. After a mean follow-up of 9 months, IPSS improved from 19.8 at baseline to 8.6 ($P < .001$). During the learning curve, persisting obstructive symptoms in four patients necessitated a second procedure. Szlauer *et al.* chose TURP, while a few other authors have reported satisfactory second procedures for persisting complaints utilizing the Tm:YAG laser in a resection technique [24]. During the learning curve of a new technique, such as any laser procedure, it is appropriate to fall back on the standard procedure. Two patients in this series developed postoperative complications (one urethral stricture and one bladder neck contracture).

Vapoenucleation

Following their work on vaporesection with thulium lasers, Bach *et al*. followed the path of holmium laser enucleation and implemented thulium lasers for this technique (vapoenucleation of the prostate) in 2009 [24]. This represented a development, because vaporesection and indeed any kind of pure Vaporization was limited to smaller glands, as the amount of tissue that can be removed by vaporization techniques is time limited, necessitating prolonged operating times with increasing prostate volume. It became obvious that for larger glands, morcellation must be an integral part of the procedure. Bach *et al*. again used a 70-W laser to remove the tissue, similarly to the previously described three-lobe technique in HoLEP [25], in 88 patients with a mean prostate size of 61.3 g. In brief, the procedure starts with the marking of the distal resection border close to the apex of the prostate. Next, two Turner–Warwick-like incisions down to the surgical capsule are made at the 5 and 7 o'clock positions up to the previously marked distal resection border. Then, the entire median lobe of the prostate is enucleated. After that, the first lateral lobe and consequently the second lateral lobe are enucleated and positioned into the bladder for morcellation. The procedure is carried out with normal saline as the irrigant. After enucleation, tissue is morcellated within the bladder.

In this study, Bach *et al*. showed that the thulium laser could be used for enucleation of prostates, as previously shown with Ho:YAG lasers. The authors discussed the advantages of this laser in comparison to open simple prostatectomy and Ho:YAG laser enucleation [25]. They reported that both intra- and post-operative course were improved. The operative time was 72 min, of which laser time (beam on) was 32.4 min. The remainder of the operative time, as in any other transurethral procedure, was taken up by instrumentation, catheterization, and morcellation. According to the authors, a suprapubic trocar could be used to perform a low-pressure procedure. An average of 127 kJ of laser energy was applied. An average of 31.7 g of prostatic tissue was available for histologic examination. The percentage of tissue lost through vaporization was estimated to be 30%, and it should be noted that the amount of retrieved tissue is often underestimated due to this fact. The average Foley catheter time was the same as in other laser procedures, being 2.1 days. Three patients (4.2%) had a high residual urine after removal of the Foley catheter and were dis-

charged with the suprapubic catheter *in situ*. At 1-year follow-up, improvements in urodynamic parameters appeared to be durable, with an increase in Qmax from 3.5 to 23.3 mL/s ($P < .001$) and decrease in PVR from 121 to 33 mL. IPSS decreased from 18.4 to 6.8. Early complications were urinary tract infection in 6.8%, hematuria in 5.6%, and need for immediate retreatment in 2.2%. One patient developed a urethral stricture. Postoperative dysuria was reported in 27%, a rate similar to that with any other ablative procedure in the prostate [26].

Open simple prostatectomy is considered the standard technique for large glands. It is effective and durable, but the severe complication rate is high. In one of the last large series of open prostatectomy, Serretta *et al.* in 2002 reported a complication rate of 15% [27]. Although the average overall complication rates for open prostatectomy and Tm:YAG laser prostatectomy appear to be comparable, the rate of severe unexpected complications, especially bleeding-related complications and transfusion rates, drop significantly with Tm:YAG laser prostatectomy. This is particularly important because surgical treatment for BPH tends to be performed in an older age group. Transfusion rates of 8.2–26.5% have been reported with open prostatectomy [28], in contrast to rates of around 1% in a large Tm:YAG series [29]. Infection occurred in 8.6% of open prostatectomies.

To overcome this problem with open prostatectomy, HoLEP was introduced for the treatment of all sizes of prostate [17]. The rate of blood transfusion is lower with this technique; reported at only 1.3% by Elzayat and Elhilali [30]. To overcome some disadvantages of the Ho:YAG laser, thulium lasers are now used for the same indication and using the same technique. The main advantage of the thulium laser is its cw-mode that allows clear cuts and therefore better vision of the surgical site. The incision in the tissue is clear and the penetration is shallow. Thus, the surgeon can cut at any desired point and is not dependent on finding the exact layer of the surgical capsule between the adenoma and peripheral zone. In case of losing this path it may be easier to return to the preferred layer using the thulium laser. For those in the early stages of learning the enucleation protocol, this may be a major problem with any other kind of laser. Clear cuts with a thulium laser therefore lead to a shorter learning curve [31].

The results of long-term follow-up for HoLEP, being the earlier introduced technique, are now available [32], but there is no reason to presume that outcomes for thulium laser enucleation will differ. Thus, thulium laser enucleation appears to be repeating the experience with Ho:YAG lasers, but with an improvement in the ability to resect and consequently a shorter learning curve. With both thulium and Ho:YAG laser enucleation (HoLEP) of the prostate, simple open prostatectomy becomes obsolete.

At this stage, three surgical protocols using thulium lasers for the treatment of BPH have been introduced: vaporization, vaporesection, and vapoenucleation. The following discussion considers subgroups of patients, cost, and recent developments in the standard protocols.

Patient subgroups

Bach *et al.* evaluated the feasibility and efficacy of thulium laser enucleation of the prostate in 65 patients with an indwelling transurethral catheter due to recurrent urinary retention secondary to BPH [33]. They were compared to 143 patients scheduled for the same procedure, but without catheterization for urinary retention. Both groups were comparable in terms of clinical parameters. On the day of discharge, the mean Qmax had improved in both groups ($P = .771$) and the PVR was similar ($P = .176$). The incidence of bleeding was similar, but urinary tract infections (UTIs) were more frequent in the catheterized group. Since up to 40% of patients scheduled for surgery for BPH can develop acute urinary retention, this study has important impact on the decision as to what intervention to perform. Compared to other laser techniques treating similar groups of patients, the thulium laser appears to offer advantages [34].

Cost

The high initial costs and prolonged learning curve are considered disadvantages of the introduction of laser techniques. As mentioned above, the learning curve with thulium lasers seems to be shorter than for other laser treatments. As far as economics are concerned, Varshney and Agrawal have argued that the lower blood loss, shorter catheter time, and decreased hospital stay offset the high initial expenditure of laser treatment, making laser treatment an attractive option even in the developing world [35]. In addition, lasers can be used in high-risk surgical patients. Especially in cardiac patients transurethral resection syndrome is not an issue, because normal saline is used as the irrigant and absorption is negligible. Patients on anticoagulation can be treated due to the superior hemostatic capabilities.

Recent developments and modifications to the standard procedure

Early studies with thulium lasers were performed with a 70-W laser, but pushed by developments in other laser systems, a 120-W thulium laser has been introduced and it has been necessary to reassess the ablative and

hemostatic properties [36]. In particular, it has needed to be clarified if the higher power would create a deeper zone of tissue coagulation and tissue penetration, which might lead to an increased risk of collateral damage. Bach *et al.* recently showed that the amount of tissue ablation increased with increased output power, but with increasing fiber diameter (800-µm fiber instead of 550 µm), the depth of the cut decreased. As shown in their previous study [20], tissue ablation with the thulium laser appeared to be more effective than reported for other systems. The recent study indicated also that the bleeding rate did not increase with the higher power output. In contradiction to that, the same group has shown that bleeding rates increase at higher power settings [36, 37].

A more interesting consideration with the higher power laser is the effect to deeper tissue layers, leading to a lower possibility of histologic assessment or even collateral damage. Using standard H&E staining, the extent of the coagulation zone with the 70-W thulium laser is reported to be 0.36 mm with the 550-µm bare-ended fiber and 0.49 mm with the 800 µm fiber [35], smaller than reported for other laser systems [38]. Deep tissue penetration is responsible for obstructive necrotic tissue, thus leading to a high reoperation rate [39]. The dissipation of heat does not end at the border of the coagulation zone. For the thulium laser, higher output power does not appear to compromise clinical results.

To overcome any compromising side effects due to penetration depth, Herrmann *et al.* have modified the prostate enucleation procedure [40]. Laser power of 90 W is used only for the incision at the verumontanum and bladder neck for removal of the middle lobe. Then, 30 W is used for coagulation of small vessels crossing the surgical capsule. The lobes themselves are liberated by blunt dissection. The rate of postoperative dysuria with this technique will be of particular interest, but clinical results are not yet available.

There have been two recent reviews of the laser treatment of prostates, including thulium lasers. Herrmann *et al.* included articles published between 1995 and 2009, and encompassing 3669 patients [41], and concluded that most contemporary laser treatments modalities provide similar Qmax improvement compared to surgical treatment. To differentiate one treatment from another, they advocated comparative computer urodynamic investigations.

Rieken *et al.* used a Medline search covering the years 2006–2009 [29]. They focused on safety, and intra- and post-operative morbidity. Best data are available for Ho:YAG laser enucleation with two meta-analyses. Photoselective vaporization of the prostate (PVP), GreenLight [potassium titanyl phosphate (KTP) or lithium borate (LBO)] is characterized by excellent hemostatic properties in patients with or without oral anticoagulation, but long-term results show a reoperation rate comparable to TURP. Thulium lasers show low intra- and post-operative morbidity, but data are limited and initial results need to be confirmed in large-scale trials [42].

Bach invited all authors of scientific thulium laser publications to define the terminology for different surgical techniques, and he proposed the use of this terminology to ensure a homogenous nomenclature [43]. In brief, the authors recommended the following terms: ThuVaP for vaporization of the prostate, ThuVaRP for resection, ThuVEP for enucleation in combination with vaporization, and ThuLEP for blunt enucleation with laser support, respectively (see Table 129.1).

Thulium lasers in the treatment of urinary tract conditions

There is less experience of the use of thulium lasers in the treatment of strictures and transitional cell carcinoma (TCC) of the upper and lower urinary tract.

Bladder neck contractures

Bach *et al.* reported on the treatment of bladder neck contractures in 14 patients using a 70 W 2 µm cw laser [44]. The unsatisfactory results with other interventions,

Table 129.1 Proposed nomenclature for thulium laser protocols (from Rieken *et al.* [41], with permission).

	Basic principle	Consensus nomenclature
Vaporization	Destruction	Tm:YAG vaporization of the prostate (ThuVaP)
Vaporesection	Resection into small tissue chips (to be washed out)	Tm:YAG vaporesection of the prostate (ThuVaRP)
Vapoenucleation	Enucleation in combination with vaporization of the median and lateral lobe	Tm:YAG vapoenucleation of the prostate (ThVEP)
ThuLEP	Blunt enucleation with laser support	Tm:YAG laser enucleation of the prostate (ThuLEP)

such as bladder neck incision either by cold knife or electrocautery, stents, or balloons, lead them to try thulium lasers. The use of lasers for the treatment of strictures was not new, but due to their operational mode and disadvantageous wavelength, they were of limited use; the coagulation zone was suspected of causing recurrent strictures. The technical features and biologic effect of thulium lasers make them more appealing for the treatment of strictures. It should be remembered that the thulium laser can cut through any kind of tissue, no matter whether perfused or scarred. Bladder neck incision also offers a good way to learn the handling of thulium lasers, as the procedure is short, bleeding does not occur, and orientation *in situ* is clear.

In Bach *et al*.'s study, bladder neck incision was carried out successfully in all patients [44]. Mean operative time and catheter time were short: 7 min and 6.5 h on average, respectively. The Qmax improved from 9 to 25 mL/s after 2 months and 23 mL/s after 12 months, while the American Urological Association (AUA) symptom score improved from 22 to 8. Two patients developed restenosis during that time.

In a much larger series of 238 patients [45], Guo *et al.* confirmed the positive results of Bach *et al.* There were no complications such as significant blood loss, urine leakage, or rectum injury. Qmax increased from 3.2 mL/s preoperatively to 16.7, 18.7, and 19.2 mL/s directly after removal of the catheter, and 3 and 5 months after the intervention, respectively. IPSS improved from 28.3 to 7.1 to 5.3, respectively. Forty-three patients developed restenosis and seven were incontinent 1–3 weeks after catheter removal. All cases of incontinence were temporary.

Ureteral strictures

Thulium lasers have been used in a completely new technique for the treatment of subtotal ureteral strictures [46]. Using a combination of endourology and fluoroscopy, the laser fiber is pulled through the stenosis "blindly." In these extreme cases of strictures, the restenosis rate was as high as 38.8%, although the rest of the group was spared from major surgical intervention. Thus, while the results of thulium laser intervention for this application are practicable, they are not superior to any other procedure.

Transitional cell carcinoma

Endoscopic management of upper urinary TCC has assumed an important role in diagnosis and treatment [47]. The well-known disadvantages of laser treatment also became obvious in the treatment of this entity; either the depth of penetration depth was too great or the pulsed mode disrupted the tissue to be treated. Consequently, Scoffone *et al*. suggested thulium lasers as an option in this type of procedure [48].

Gao *et al.* has reported the use of thulium lasers for the treatment of recurrent bladder tumors [49] a condition for which transurethral resection of the bladder (TURB) is considered to be the standard procedure. According to the authors, histology may not necessarily be required in these cases. They performed thulium laser resection of bladder tumors (ThuRBT) via flexible cystoscope in 32 patients. All patients were treated successfully with no hemorrhage, obturator nerve reflex or vesicle perforation. Biopsies taken after the procedure revealed no residual tumors. During the first year of follow-up, local and heterotopic recurrences were found in three and six patients, respectively. The accumulated recurrence rates at 3, 6, and 12 months were 9%, 22%, and 28%, respectively. In conclusion, this first report on treatment of recurrent superficial bladder cancer via flexible cystoscope appears to be promising. Furthermore, it can be performed as an outpatient procedure.

Other transurethral procedures

There has been recent interest in the use of thulium lasers in other than transurethral procedures, due to their shallow depth of penetration and good coagulation abilities. Mattioli *et al.* reported on their initial experience with partial nephrectomy, either open or laparoscopically, in nine patients [50]. In six patients, the big vessels were clamped, while in three they were not. Mean tumor size was 3.5 cm and mean operative time was 135 min for the open procedure and 210 min for the laparoscopic procedure. Blood loss was 260 mL in the open procedure and 156 in the laparoscopic procedure. One case was done under renal hypothermia. The authors were able to outline the precise dissection as there was an absence of bubbles and minimal formation of gas during the laparoscopic procedure. The laser coagulated vessels up 1.6 mm, which allowed good sealing of the surface. Operation time was relatively short because suturing of renal parenchyma was not required. Gruschwitz *et al*. have also reported successful results for Tm:YAG laser-supported partial nephrectomy [51]. These observations are underlined by an animal study of partial nephrectomy using a natural orifice transluminal endoscopic surgery (NOTES) procedure [52]. Liang *et al.* have investigated *ex vivo* how to overcome the problem of smoke formation during laser procedures [53].

Conclusions

The development of laser technology from the cradle of modern physics in 1900 by Planck to its latest medical

boundaries is an exciting example of how basic physics finds its way into clinical practice. Detailed knowledge of technical aspects has lead to great improvements in laser devices and consequently better medical treatment. Thulium lasers in this respect can be seen as a further development of Ho:YAG lasers. Its cw-mode leads to a faster learning curve, and consequently many benefits of Ho:YAG procedures can be brought to a larger community of users [54].

CHAPTER 130
Interstitial Laser Therapy

Rolf Muschter
Department of Urology, Diakoniekrankenhaus Academic Teaching Hospital, Rotenburg, Germany

Introduction

Interstitial laser therapy of the prostate, also called interstitial laser coagulation (ILC) or laser-induced interstitial thermotherapy (LITT), was originally developed to generate coagulation necrosis of a large volume *inside* the adenomatous tissue of the prostate, without damaging the urethra and internal sphincter, to achieve a physiologic volume reduction of the obstructive prostate tissue by secondary atrophy rather than by tissue sloughing. After some years of clinical experience and growing knowledge on ILC and related techniques, such as transurethral needle ablation (TUNA), it became obvious that the laser energy that is administered by placing a laser radiation applicator inside tissues ("interstitial" laser application) can achieve different quantitative and qualitative effects, and in the case of treating benign prostatic hyperplasia (BPH) different clinical effects may occur. These depend not only on the type of laser source, laser applicator, and irradiation parameters, but also particularly on the "treatment scheme" (e.g. number of applicator placements) the surgeon is following. ILC is surgeon dependent. Therefore, interstitial laser therapy can be performed as a procedure in which a large tissue volume is coagulated with or without preserving the urethra, resulting in a significant volume reduction of the prostate and a TURP-like cavity. It can also be performed using the same laser, applicator, and irradiation parameters, but resulting in a low-volume coagulation. If the first type of interstitial laser therapy, "high-volume" ILC (HV-ILC) is performed, the surgeon may achieve a clinical effect comparable to transurethral resection of the prostate (TURP); in the second type, "low-volume" ILC (LV-ILC) or LITT, any clinical effects that may occur are probably unrelated to volume reduction or tissue ablation [1]. Unfortunately, the literature published to date does not discriminate between HV-ILC and LV-ILC, nor does it mention that ILC is a procedure whose clinical outcome depends highly on the surgeon. The terminology used in the past does not even reflect these differences.

If laser energy is administered by irradiating an outer or inner surface, e.g. in transurethral free-beam laser application such as visual laser ablation of the prostate (VLAP), the amount of tissue that can be necrotized is limited by two factors: the relatively shallow penetration depth of the laser radiation and the limited size of the organ surface that is accessible [2–4]. By contrast, in interstitial laser irradiation the applicator can be inserted into the desired tissue as deep and as often as necessary to coagulate any amount of tissue.

Clinical outcomes, namely symptomatic improvement, voiding parameter improvement, and complications, depend not only on surgical technique and strategy, but also on biologic action. For unknown and unforeseeable reasons in some individual cases, the necrotic tissue may remain in place, necessitating resection.

Indications

Patients selected for interstitial laser therapy have moderate-to-severe lower urinary tract symptoms (LUTS) and mild-to-moderate, or with HV-ILC even severe, bladder outlet obstruction (BOO) related to BPH, with moderate-to-pronounced benign prostatic enlarge-

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

ment (BPE), and would otherwise be candidates for surgical intervention, either transurethral or open, or other minimally invasive or laser procedures. In principle, there is no limit to the prostate volume that can be treated by this approach; even large middle lobes can be treated [5]. Concomitant diseases, such as strictures of the urethra or bladder calculi, can be treated in the same session.

Patients with chronic urinary retention or poor detrusor function will need to have a catheter in place for a longer period after the procedure because of the time required for the prostate to shrink sufficiently to clear the obstruction. Of course, longer catheterization is necessary in any type of treatment in which there is no immediate tissue removal (secondary tissue ablation).

Virtually no intraoperative morbidity is associated with interstitial laser therapy and in principle it can be performed with the patient under local anesthesia (given that it appears acceptable to perform a cystoscopy with minor transurethral manipulation under local anesthesia) [6, 7]. Thus, even high-risk patients who are not candidates for transurethral resection need not be excluded from this treatment modality. Recurrent or residual BPH after previous prostate surgery, laser treatment, or microwave treatment can also be treated by ILC.

Although ILC alone is a sufficient treatment, in smaller prostates with median bar obstruction, an additional incision of the bladder neck may be useful [8, 9]. This can be done at the 5 and 7 o'clock or at the 6 o'clock positions using either a Collings knife or a bare laser fiber. Other combination treatments, such as ILC of the side lobes plus subtotal transurethral resection (e.g. of the median lobe), may be beneficial for selected patients to shorten postprocedure catheter time. An interesting concept might also be the combination of ILC and TURP, with ILC performed just before standard TURP in order to improve hemostasis. The combination of simultaneous interstitial laser therapy and VLAP may increase the efficacy of each procedure, but no major series have been published on this combination. The combination of ILC with temporary stents has been much discussed, but no major study has been reported on this either. A few reports have demonstrated the feasibility of interstitial laser ablation using the holmium (Ho):YAG laser [10–12].

Antegrade ejaculation was preserved in approximately 80% of patients who underwent the laser procedure [13–18]. This represents a significant improvement over TURP, but the risk of retrograde ejaculation after interstitial laser therapy cannot be eliminated completely.

Interstitial laser therapy should therefore be the first choice for high-risk patients who need surgical intervention and for patients who require surgical treatment but in whom it is essential to minimize surgical risks. Patients desiring rapid symptom relief after treatment should be excluded from laser coagulation therapy and preferably treated with TURP, laser vaporization or laser resection/enucleation [19].

Patients whose primary concern is normal ejaculation should be treated medically. If surgery for them is unavoidable, interstitial laser therapy is one treatment of choice and there is a very fair chance of preserving ejaculation. The surgeon can increase this chance by not treating the bladder neck; however, this carries the risk of a suboptimal correction of voiding symptoms. In any case, the patient should be advised that the loss of prograde ejaculation is a possible side effect of interstitial laser therapy.

Patients with obstructive symptoms from carcinoma of the prostate are also candidates for interstitial laser therapy [20]. The indications are the same as those for palliative transurethral resection to treat BOO, such as locally advanced disease. However, interstitial laser therapy is definitely not an alternative to radical prostatectomy or curative radiotherapy.

Patients with symptomatic BPH who are suspected of having prostate cancer because of their elevated serum prostate-specific antigen (PSA) level, but who are not candidates for curative treatment, can be treated with ILC, but they should have a biopsy of the prostate immediately after but during the same session as treatment. If curative therapy is possible, a screening biopsy should be performed and evaluated before laser treatment. If biopsy results are positive, the patient should not receive interstitial laser therapy.

Patients who have bladder cancer close to or at the bladder neck or in whom invasion of the prostate is uncertain should not receive interstitial laser therapy. The procedure is also contraindicated in cases of acute prostatitis or epididymitis and when there is an abscess of the prostate. Chronic prostatitis, however, which is frequently present in BPH patients, is not a contraindication to interstitial laser therapy.

Patient preparation

As in most minimally invasive modalities for the treatment of BPH, in interstitial laser therapy no tissue is sampled for pathologic examination. Therefore, a digital rectal examination and serum PSA level evaluation are essential. If either of these is suspicious of cancer, a transrectal ultrasound (TRUS) examination and a screening biopsy should be performed before or after interstitial laser therapy, depending on the patient's age and physiologic status, and the potential treatment consequences.

A patient with an active urinary tract infection (UTI) must be treated with appropriate antibiotics before

interstitial laser therapy. Patients with acute epididymitis or acute prostatitis should not undergo interstitial laser therapy until they have completely recovered from these conditions. If there is significant postvoid residual urine volume (PVR) or if the patient has chronic or acute retention [21], a suprapubic or Foley catheter should be inserted and left in place after treatment until voiding is sufficient. Routine perioperative antibiotic prophylaxis is recommended [14] to produce sterile urine preoperatively, particularly if a prostate biopsy is to be performed transrectally at the time of laser therapy.

As in any other BPH treatment, the success of interstitial laser treatment should be monitored during follow-up. Therefore, the patient's American Urological Association (AUA) symptom score, maximum urinary flow rate (Qmax), PVR, and prostate volume should be measured before treatment. Additional urodynamic measures (pressure–flow studies) are helpful for assessing the decrease in obstruction after laser therapy.

The common diagnostic procedures usually required for TURP are sufficient for interstitial laser therapy. Special radiologic or endoscopic examinations are not necessary. In general, it is recommended to follow the specific guidelines for the diagnosis of BPH.

As for other procedures, informed consent should include information about the different treatment options, including transurethral resection, and the specific advantages, disadvantages, risks, and potential complications of each method. Patients should be informed that surgical risks, such as significant bleeding or TUR syndrome, are rare or nonexistent. The chance of the patient retaining normal sexual function is approximately 80% [22, 23]. The patient should be aware that the failure rate for this procedure is about 10–15% within 1 year (for an unselected group of patients) and that postprocedure catheterization (permanent or intermittent [24]) will be necessary for some time. The patient should know that at present the longest follow-up is only 10–12 years and publications on long-term results are available for follow-up of 4, 5, and 7 years only [25–27].

Published reports of the complications associated with interstitial laser therapy and their incidence include complicated UTI with fever or epididymitis or prostatitis (0.5%), transient stress incontinence (0.1%), urgency, and strictures of the urethra or bladder neck (2–5%), including recurrences of pre-existing, simultaneously treated strictures [13–16, 22, 23, 28, 29]. More frequent are uncomplicated UTIs in about 10–35% of patients and transient irritative symptoms in 9–15%; tissue sloughing also has been noted. Permanent incontinence has never been reported but should not be excluded from the list of potential risks.

Some risks can only be theorized, such as coagulation of the rectum with consequent fistulas, damage to the neurovascular bundle, and fiber breakage during irradiation that produces fiber fragments that must be removed by electroresection. With correct application techniques and equipment, these risks can be avoided. The incidence of these risks, however, has not been reported.

Preoperative preparation

Interstitial laser therapy can be performed with a local [6, 7], regional, or systemic anesthetic. If local anesthesia is chosen, such as by transperineal injection of lidocaine to achieve a blockade of the prostate and pudendal nerves, overfilling of the bladder, which could cause discomfort, should be avoided. Although no permanent irrigation is necessary during this procedure, a suprapubic catheter can be useful.

After adequate anesthesia is induced, the patient is placed in the dorsal lithotomy position. Routine disinfection and a noninflammable drape, as generally required for any laser surgery, should be used. If not previously done, a routine urethrocystoscopy is performed. A video camera and monitor are useful, but are not required. All general laser safety measures (e.g. warning signs and signals, and wavelength-specific eye protection) must be observed before, during, and after interstitial laser therapy.

Interstitial laser applicators can be placed using several different approaches [16, 30]. In practice, endoscopically-controlled transurethral placement has proved most useful. Neither percutaneous placement from the perineum nor transrectal placement guided by TRUS was used in the most recent series.

Instrumentation

Several laser wavelengths have been studied for use in interstitial laser therapy [10–12, 28, 31–35]; published reports have demonstrated that 800–1100-nm wavelengths offer relatively deep penetration depths in water and efficient volumetric heating, which permit the delivery of necrotic temperatures deep into tissues. These wavelengths can be delivered with flexible optical fibers; consequently, Nd:YAG lasers (1064 nm) were first used for interstitial laser therapy [36–40]. Experiments have shown that diode lasers emitting at approximately 805, 830, 940, and 980 nm, and even the Ho:YAG laser (2100 nm), are also suitable for generating large interstitial coagulation volumes [10–12, 28, 31–35].

Bare fibers, as used by Littrup *et al*. [41, 42] and McNicholas *et al*. [43] in animal experiments to evaluate interstitial laser therapy for prostate cancer and later by McNicholas *et al*. [30, 44–48] for BPH treatment, emit all laser energy from a very small area (0.3 mm^2 with a 600-µm fiber). Even with low-laser power, high-power

densities are achieved (330 W/cm^2 with 1 W), leading to immediate carbonization and vaporization. Experiments have demonstrated that interstitial irradiation with a bare fiber at up to a 20-W power setting produces only a small spherical lesion of 5–10 mm diameter, consisting of a central cavity filled with debris, and adjacent char and a small coagulated rim [30, 38–40, 49, 50–55]. For LV-ILC this may be sufficient. To achieve HV-ILC, a very high number of applications is required.

To avoid charring and to achieve large-volume coagulation, the power density of an interstitial applicator must be much lower (5–10 W/cm^2) [40, 56]. Since Bown first discussed interstitial laser therapy for cancer treatment in 1983 [57], several types of applicators with larger irradiating surfaces have been used in laboratory or clinical experiments [35, 53, 58–65], but these have all produced similarly unimpressive results.

Interstitial laser therapy for BPH was a completely new concept, first described by Hofstetter and Muschter and coworkers [36, 37, 39, 49]. New types of applicators were specially designed. Two technical principles have been elucidated to extend the emitting surface [56, 66]. One solution is a diffusor tip that emits the radiation circumferentially and randomly in all directions in a more or less even pattern along the entire length of the applicator [66]. The other solution is a system emitting the laser radiation circumferentially in a forward direction (with a ring- or cone-shaped beam profile at an angle of approximately 45° in water). This is achieved by eliminating the transversal modes of the laser beam [56]. In tissue, through light reflection and predominantly scattering, the latter type of applicator acts almost like a diffusor tip, too. Both types of applicators create rather homogeneous coagulation zones around the emitting tip. These increase in size by conduction of heat to the periphery. Their final shape is ovoid, ellipsoid, or spherical [3, 31, 32, 40, 49]. Lesion length depends on the emitting length of the applicator; the radius of the lesion can be up to 1 cm (i.e. up to a diameter of 2 cm), depending on laser wavelength, laser power, and radiation time (*in vivo* maximal single lesion volume approximately 4–10 cm^3) [3, 40, 49, 67–77].

Interstitial applicators consist of an emitter (e.g. transparent quartz glass cylinder or Teflon coating) affixed to the distal end of a flexible 600-μm quartz glass fiber, with a specific cut of the tip in some types. Different dimensions have been tested; for routine use in the prostate, an emitter length of 2 cm and a diameter of approximately 2 mm were found to be the best compromise based on the technical requirements (large radiating surface) and surgical requirements (small size for simple handling). For ease in placement, the tip of the applicator is exaggerated [49]. The actual design of the interstitial applicators may vary among manufacturers [35, 56, 66, 78, 79].

The goal of interstitial laser therapy is to achieve a relevant coagulation volume in the shortest time. Although this can be achieved with multiple (successive or simultaneous) applicator placements, each single treatment volume should be large. Therefore, radiation parameters must be chosen to fulfill this requirement. Optimal parameters vary for different laser wavelength and applicator combinations [3, 28, 31–33].

Using constant laser power in the range 5–7 W, the maximum coagulation volume can be expected within approximately 10 min of irradiation time, without the risk of carbonization [37, 39, 40, 49]. Some laser/applicator combinations may be operated with a constant power of up to 10 W for 10 min.

More rapid heating by using higher laser power will reduce irradiation time but increase the risk of carbonization, or even make carbonization a certainty if the power density is above the carbonization threshold. For short irradiation times, however, high powers are tolerable. Therefore, various power formatting programs were designed and tested to achieve the maximum coagulation volume within the minimum total irradiation time [3, 31–33]. In this type of laser energy application, irradiation starts with a relatively high power that is reduced in repeated steps or continuously to maintain the temperature in the center of the lesion at the highest level just below the carbonization threshold. This allows further energy influx to increase the size of the lesion, and this power is maintained until a temperature balance is reached in the periphery [3].

A feedback system further optimizes energy application; in such a system, the actual emitted laser power depends on the temperature generated and measured at the applicator ("Indigo 830e"; Johnson & Johnson, New Brunswick, NJ, USA). Different optical feedback devices are also available for detecting carbonization at the applicator tip, thereby preventing thermal damage to fibers by automatically terminating laser irradiation.

The Ho:YAG laser can also be used in combination with an applicator specifically designed for interstitial laser therapy ("Auriga"; Wavelight, Starnberg, Germany). Experiments have demonstrated that lesion volumes equivalent to those achieved with the Nd:YAG or diode lasers can be generated by using high-pulse energies and relatively long pulse durations. Sufficiently large lesions were achieved in relatively short application times (usually 1 min, and in later experiments only 10 s) [10, 12]. Depending on the pulse frequency, the average laser power can be calculated. Interstitial lesions generated with the Ho:YAG laser consist of a central cavity and an adjacent zone of coagulation.

To achieve large lesions inside the prostate lobes, the laser applicator needs to be placed deep inside [80, 81]. The ideal angle would be perpendicular; however, in reality in transurethral placement, the applicator is

rather tangential. Because the laser fiber is flexible with a rigid or fragile tip, if not properly guided, the fiber may slide along the surface, bend, and even break. Transurethral interstitial laser therapy requires a rigid scope with a working channel large enough to accommodate the fiber, usually between 5F and 7F. The viewing angle of the scope can range from 0º to 30º. An ideal instrument has a small separate working channel that ends at the level of the telescope for optimal stabilization of the fiber during puncture, such as the atraumatic urethrocystoscope described by Miller *et al*. [82] or the Gilling laser resectoscope. If a standard cystoscope with the usual "half-pipe" sheath tip is used, rotation may improve fiber placement.

Continuous irrigation is not required throughout the procedure. While placing the applicator, irrigation will optimize visualization of the prostate and laser fiber. Any sterile irrigation fluid can be used, such as saline solution or water. Auxiliary instruments for placing the fibers are not necessary. Any type of urinary catheter can be used for bladder drainage.

For percutaneous (perineal) interstitial laser therapy, a TRUS scanner is helpful [83], preferably one with an aiming device (e.g. template) as is used for the perineal placement of seeds for local radiation therapy of prostate cancer. For penetrating the skin and guiding the fiber into position within the prostate, a special cannula large enough to accommodate the applicator is used. With an outer diameter of approximately 2.1 mm and a sharpened tip, this cannula can be inserted without dilation [13, 14, 16, 40].

Operative steps (Figures 130.1 and 130.2)

The steps of the transurethral and perineal approaches are listed in Tables 130.1 and 130.2, respectively.

Technique

The goal of HV-ILC is to necrotize a large volume in each lateral lobe and the median lobe (if needed) to produce therapeutic results while preserving healthy tissue. The total number of fiber placements is dictated by the total prostate volume and configuration, but is ultimately dependent on the discretion of the surgeon. Any number of placements can be used. Generally, it is better to treat one extra site than one too few, because some overlap of the lesions needs to be taken into account. A general guideline is one to three applicator placements for each estimated 5–10 cm^3 of BPH tissue [15, 84–86]. Individual placements (in the tissue, not points of puncture) of the laser fiber should be spaced by about 0.5–1 cm and at different angles to minimize substantial overlap of treatment volumes (which is not harmful but wastes time), but be close enough so there are no gaps of untreated tissue. The points where the fibers are inserted can be close to each other.

While the final result of a successful HV-ILC regarding prostate volume reduction and decrease of BOO can be compared with TURP, LV-ILC is comparable to TUNA or transurethral microwave thermotherapy (TUMT) [1]. The treatment effect of LV-ILC is predominantly symptomatic improvement and is probably not related to volume reduction, but to potential destruction of afferent nerves, although this is not based on experimental data [87, 88]. The goal of LV-ILC is to generate symptomatic improvement in mildly obstructed patients with no or few unwanted side effects [89], such as the requirement of other than local anesthesia and the need for prolonged catheterization. The application technique is identical to that for HV-ILC, but with fewer numbers of fiber placements and/or different laser parameters (e.g. lower laser power, shorter irradiation time).

Fiber placement is basically limited by the proximity of the treatment volume to be produced to the prostatic urethra, prostatic capsule, and points along the prostatic urethra distal to the bladder neck and proximal to the external sphincter. With the ultrasound-guided perineal approach, this can easily be achieved by measuring and keeping the distance between the applicator and the urethra or the capsule on all sides at approximately 1 cm (the expected radius of coagulation). Likewise, staying within the limits with the transurethral approach is not difficult.

In general, the sites for fiber placement should be chosen where the mass or bulk of hyperplastic tissue is found. In the sagittal plane, fiber penetration should be in the direction of the urethra. With the patient in the lithotomy position, the direction of the prostatic urethra in most cases is approximately parallel to the operating table at the apex, turning ventrally near the bladder. Therefore, in the apical zone it is best to puncture the lateral lobes at the 3 and 9 o'clock positions, and penetrate parallel to the operating table. When closer to the bladder neck, it is suitable to penetrate more ventrally at the 10 and 2 o'clock positions. In larger prostates, multiple punctures at different fan-shaped angles are required.

It may be important to preserve the urethra to minimize symptoms following the procedure [90]. If the urethra is accidentally necrotized, however, ordinary tissue sloughing may occur and is not harmful (the treatment effect is then much like that of deep transurethral free-beam coagulation) [13–16]. Avoiding damage to the urethra requires both a minimum depth and angle of fiber penetration. The applicator should be inserted to a depth of at least 0.5 cm beyond the irradiating part. In most types of applicators, this corresponds to their proximal end, and in others to a fiber depth marker. The

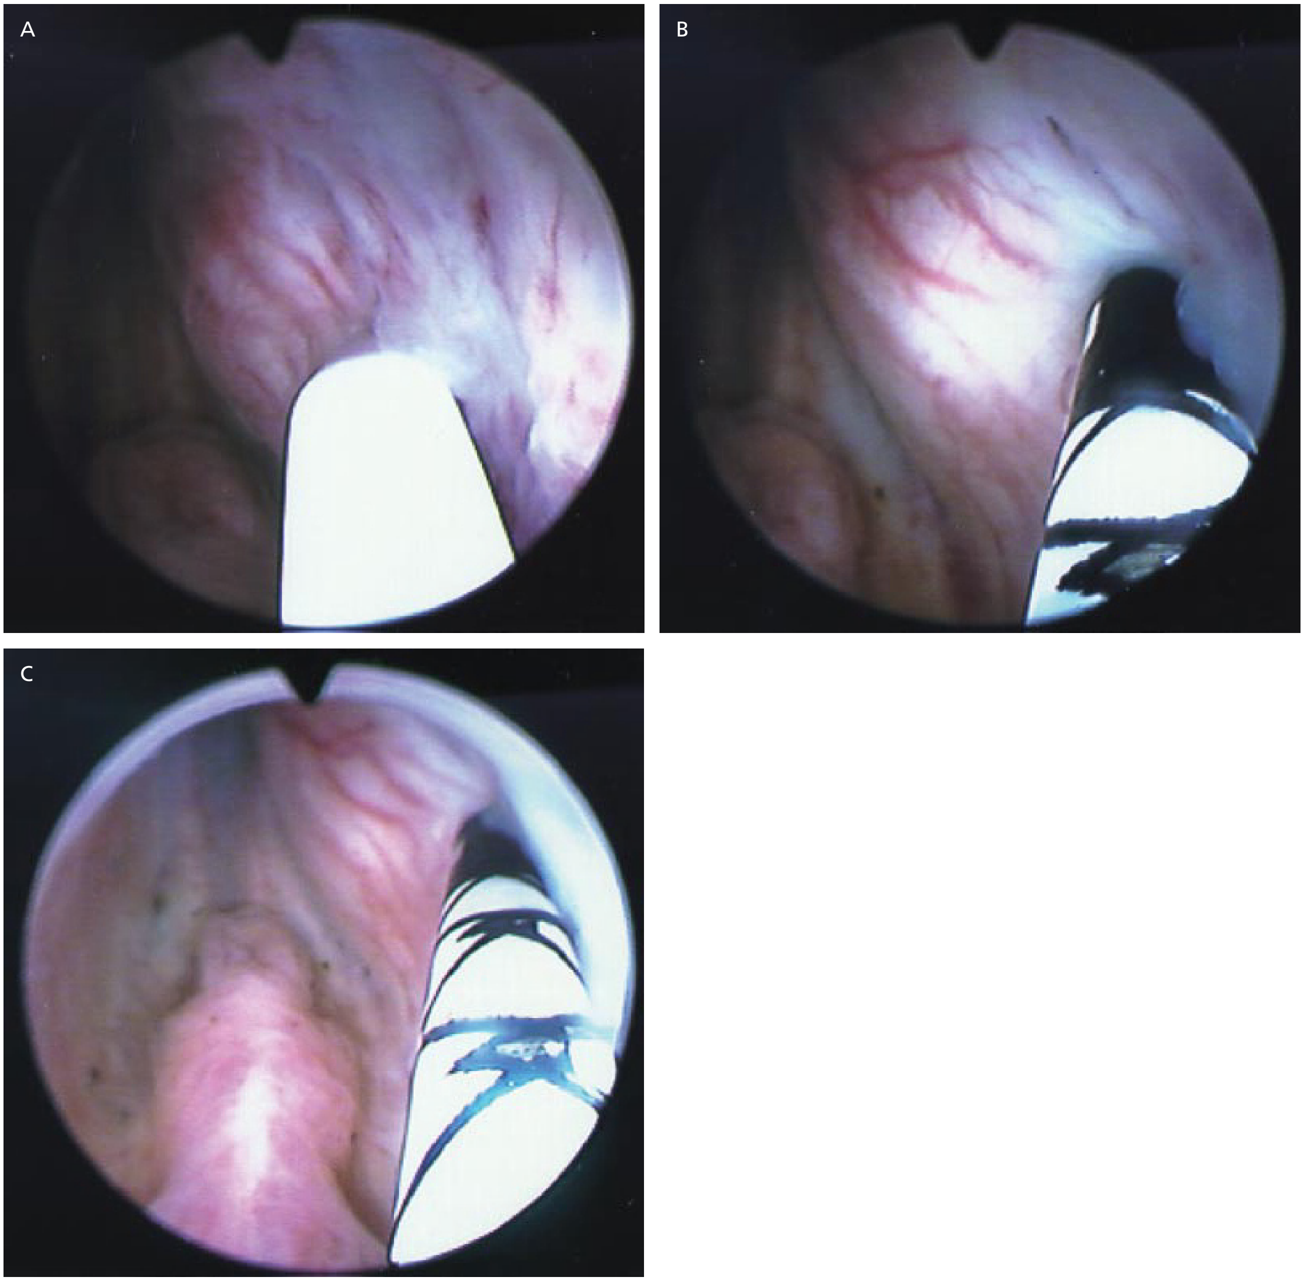

Figure 130.1 (A) Interstitial applicator just before insertion into the apical portion of the left lateral lobe. (B) Interstitial applicator completely inserted in the apical portion of the left lateral lobe, dorsal part. (C) Interstitial applicator completely inserted in the apical portion of the left lateral lobe, ventral part.

fiber penetration angle in relation to the longitudinal axis of the urethra should be the maximum achievable; in the apical zone this is approximately 45°. Closer to the bladder neck it is often less (20° in large prostates) because of the convex shape of the lobe. For effective treatment of this part of the lobe, it is also possible to insert the fiber at a point closer to the apex at a lower angle, and then carefully to penetrate deeper toward the bladder neck.

Coagulating the prostate capsule is unnecessary and should be avoided. In practice, fiber penetration to the lateral or ventral parts of the capsule is almost impossible because of the limited penetration angle and depth achievable, but it is probably not harmful or of clinical significance if it does occur. In addition, the highly vascular nature of the prostate capsule acts as a heat sink and contributes to preventing potential coagulation of the capsule itself and adjacent structures. However, for

Table 130.1 Operative steps in the transurethral approach.

1.	Administer local anesthetic or initiate spinal or general anesthesia
2.	Prepare the operative field and instruments
3.	Instill lubricant gel into the urethra, connect the cystoscope to a light source and an irrigation container, and attach a video camera to the scope if appropriate. Insert and advance the cystoscope under direct vision into the bladder
4.	Fill the bladder and place a suprapubic catheter if appropriate
5.	Empty the bladder
6.	Attach the laser fiber connector to the laser aperture
7.	Activate the laser unit and set it in the standby mode
8.	Insert the applicator into the cystoscope's working channel and advance it until it is visible
9.	Retract the cystoscope and fiber together back into the prostatic urethra (wide angle view)
10.	Choose a treatment point and advance the fiber to be just in contact but not penetrating the urethra. Hold the cystoscope's tip close to the treatment point and advance the cystoscope if necessary (almost to or to tissue contact)
11.	Tilt the cystoscope laterally in the desired angle from the center axis of the urethra. In the sagittal plane, keep the cystoscope aligned in the direction of the urethra or, in voluminous lobes, angle it ventrally or moderately dorsally
12.	Advance the fiber to puncture the urethra (Figure 130.1A). Observing the applicator's proximal end or fiber depth marker, insert the applicator completely or further to the desired depth (Figure 130.1B)
13.	Activate the laser beam for the prescribed treatment duration
14.	Set the laser in the standby mode. Retract the applicator into the cystoscope (Figure 130.2)
15.	Repeat steps 10 through 14 at additional sites (Figure 130.1C) within the same and other prostate lobes until the desired volume of tissue has been treated. The order of punctures should follow a scheme
16.	Inactivate the laser unit and remove all instruments
17.	Place a transurethral catheter if appropriate

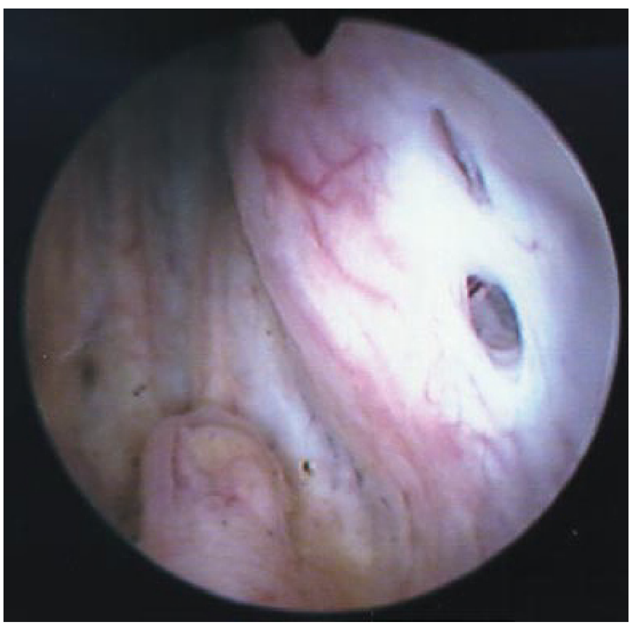

Figure 130.2 Puncture sites at the apical portion of the left lateral lobe, after removal of the laser fiber.

Table 130.2 Operative steps in the perineal approach.

1.	Administer local anesthetic or initiate spinal or general anesthesia
2.	Prepare the operative field and instruments
3.	If necessary, perform a urethrocystoscopy. Place a suprapubic or transurethral catheter
4.	Insert the transrectal ultrasound scanner and scan the prostate. Attach the aiming device (template)
5.	Attach the laser fiber connector to the laser aperture
6.	Activate the laser unit and set it in the standby mode
7.	Choose a treatment point, insert the trocar cannula, and advance it to the desired depth and location under ultrasound guidance
8.	Remove the trocar, insert the applicator into the cannula, and retract the cannula
9.	Activate the laser beam for the prescribed treatment duration
10.	Set the laser in the standby mode; remove the applicator
11.	Repeat steps 7 through 10 at additional sites within the same and other prostate lobes until the desired volume of tissue has been treated
12.	Inactivate the laser unit and remove all instruments

maximum safety, the applicator should not be advanced dorsally because there is little or no BPH tissue to treat and yet there is a potential risk of damaging structures adjacent to the prostate (e.g. neurovascular bundles and rectum) or inducing subtrigonal lesions with subsequent (relative) bladder neck strictures.

All puncture points must be within the length of the prostatic urethra between the external sphincter and the bladder neck. The puncture point closest to the bladder neck should be no closer than 1.5 cm from the bladder neck, so that it will not penetrate the bladder (except for treatment of a median lobe). Accidental penetration of the applicator through the prostate into the bladder can be detected by feeling resistance to fiber penetration. If the laser is activated and the bladder is full, there is no effect because of light diffusion and low laser power. If

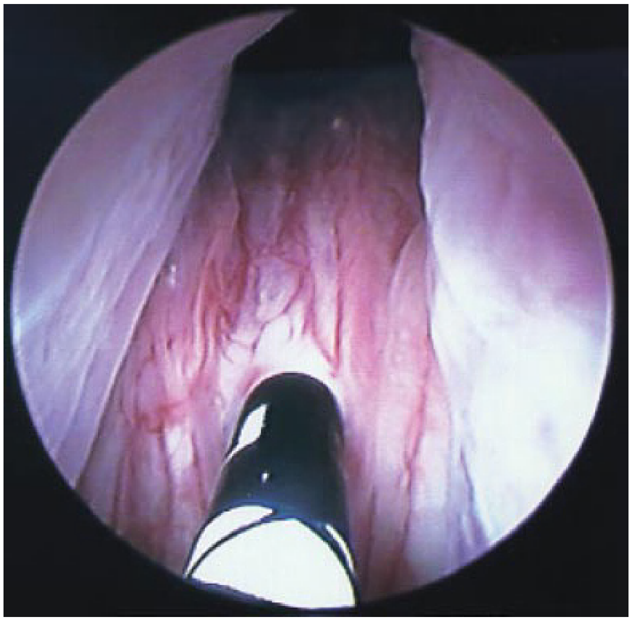

Figure 130.3 Puncture site for treating the center of the median lobe.

the bladder is empty and the fiber is in contact with the bladder wall, there is a chance of coagulating the bladder wall, which can be, but is not necessarily, a problem. If fiber penetration occurs, the fiber can simply be pulled back into the prostate and that site can be treated. The most apical puncture point should be in the prostatic urethra just in front of the proximal end of the external sphincter (see Figure 130.1) so that no apical tissue goes untreated. As discussed earlier, care must be taken to insert the applicators to the required depth.

When the median lobe is being treated, the fiber should be advanced in the direction of the bladder (Figure 130.3) to prevent subtrigonal penetration. A large median lobe should be treated with more than one puncture [5]. Depending on its size and shape, punctures can be made at different levels and angles. When puncturing the median lobe, pressure on the fiber usually pushes it towards the bladder before it penetrates; therefore tangential placement of the fiber may result. This can be avoided by a moderately dorsal direction of puncture. For the effective treatment of a median lobe, several fiber placements are necessary because of the large surface area that is cooled by the fluid in the bladder.

Adopting an order scheme for punctures can be helpful. There can be any starting point: bladder neck, apex, median lobe, or lateral lobe. If the first lesion is produced in the apex, the prostate becomes a little harder in that area because of coagulation. This firmness facilitates subsequent penetrations toward the bladder neck, which is a little more difficult to reach because of the limited space in the prostatic urethra.

While laser energy is being delivered into the prostate tissue through the applicator, it is better to stabilize the fiber and cystoscope by holding them manually rather than mechanically anchoring them (e.g. with a tripod). If a mechanical anchor is used, patient motion could pull the fiber out of the prostate.

Bleeding at a treatment site is usually slight or nil. Irrigation keeps the field clear. Deep punctures may bleed after the fiber is withdrawn because not all of the puncture channel is coagulated. Typically, all bleeding stops in a short time, and cautery is usually not required.

If a laser feedback system is used and detects carbonization during treatment [91], it will terminate irradiation at that treatment site. The applicator should be withdrawn and inspected. Usually it can be cleaned and used for subsequent treatment sites. Burned fibers should not be used again because fiber damage increases rapidly with subsequent use. Resumption of treatment with either the same or a new fiber should always proceed at a new puncture spot.

Approaches other than those already described are the transrectal [16, 30, 92] and the laparoscopic/pelvioscopic approaches [16]. The transrectal approach has no advantages over the perineal approach, but entails risks such as infection or bowel injury [30], so the latter approach may be suitable for the treatment of cancer but seems to be too aggressive for BPH.

On-line treatment control is possible with the use of magnetic resonance imaging (MRI) [75, 93, 94], as shown by several authors treating malignancies with interstitial laser therapy [20, 71, 72, 95–97]. In the treatment of cancer it is critical to leave malignant tissue untreated and therefore on-line treatment control is required; in BPH treatment, however, this would be too costly and is not necessary. TRUS is not suitable for on-line control because changes are detectable only when tissue is carbonized or vaporized. Multichannel rectal temperature monitoring can be performed for additional safety; direct temperature measurements in several patients in the tissue, prostate capsule, and rectum [13–16, 40] proved that (1) the desired temperatures with temporal and spatial distributions, as expected based on animal experiments [3, 4, 49, 98], were achieved in the treatment volume [99]; and (2) that no critical increases in temperatures were detectable in the capsule or surrounding organs, in particular the rectum [40]. Computerized calculations or simulations of the temporal and spatial temperature profiles [100, 101] provide no additional information and are not required for monitoring interstitial laser therapy of BPH.

Animal experiments have demonstrated that the combination of a systemically or locally administered photosensitive drug and laser therapy using a specific laser wavelength and a nonthermal energy range [photodynamic therapy (PDT)] could be useful for treating BPH

[102]. Early trials with interstitial PDT using different photosensitive agents were undertaken some years ago to treat prostate cancer [103, 104]. Although no major breakthrough was achieved, the concept seems promising but requires further investigation.

Postoperative care

Following interstitial laser therapy, a catheter (either a 10F or 12F suprapubic catheter or a 14F or 16F urethral catheter) is left in place to provide urinary drainage. Since bleeding seldom occurs, bladder irrigation is usually not required but can be useful in individual cases for a few hours to prevent clot retention.

Heuck *et al*. [69, 70] and Mueller-Lisse *et al*. [73, 75–77] report that postprocedure MRI demonstrates a marked increase in prostate volume, returning to the preprocedure value within about 5–7 days. In addition, because of the coagulation, the consistency of the prostate tissue becomes firmer, thus usually resulting in a temporary increase in the degree of obstruction. Consequently, voiding function and obstructive symptoms are usually temporarily worse, somewhat correlating with the coagulation volume. Therefore, the majority of patients require urinary drainage for a few days. Patients with moderate-to-good detrusor function are able to compensate for the acutely increased obstruction. In this group, the catheter can be removed early. Patients with chronic retention or with poor or decompensated detrusor function, however, will require the catheter for a longer time. In principle this is not specific to interstitial laser therapy but applies to all procedures without substantial immediate tissue removal. The need for and duration of catheterization is different in HV- and LV-ILC [79].

If a transurethral catheter is used, it should be taken out after 3–7 days. Patients who fail to void should be catheterized for another week. If a suprapubic catheter is used, it is usually clamped on the first day. Continuous voiding training can be done during the day with regular control of the PVR, while at night sufficient drainage can be achieved. If voiding function becomes satisfactory, the suprapubic catheter should be removed. This can be expected within 1 week for most patients.

During the weeks following HV-ILC, a continuous volume reduction of the prostate is observed with shrinking of the coagulated lesions [13–16, 40, 49]. Only small residues are detectable after 6 weeks and vanish completely within another 4–6 weeks [69, 70]. In this period symptoms and voiding function continue to improve in most patients. A few patients show a more stepwise, often dramatic, improvement that can occur at any time during follow-up, even after 3 months.

Subjective satisfaction is usually achieved within 2–6 weeks, and a substantial objective improvement in Qmax and prostate volume in HV-ILC can usually be measured after 4–8 weeks. The final outcome can be judged after approximately 3 months.

Results

Several studies have indicated the effectiveness of interstitial laser coagulation of BPH regarding all of the three characteristics of the disease: symptoms, obstruction, and enlargement [9, 13–16, 29, 105–111].

In the initial study, 239 patients were treated at Grosshadern Hospital of Munich University from July 1991 through October 1993 [13–16]. During this time, many technical and procedural improvements were made and the difficulties that arose during the learning curve were overcome. The results were encouraging and compared well with published reports of TURP; in fact, the results were superior to most other alternative treatment modalities of that time [14, 17, 110]. The multivariate analysis showed no factors predicting final success or failure, such as initial symptoms, flow rates, residual volumes or prostate volumes, and endoscopic or perineal access, except the number of cases previously performed by the surgeon (reflecting the learning curve). Interstitial laser therapy was safe, with a low potential for severe side effects. Retreatment for persistent voiding problems was necessary within 1 year in 9.6% of patients. For the early treatment group, follow-up was up to 30 months at the time of evaluation, with only a few more patients requiring retreatment. In Japanese studies, Arai *et al*. found a strong correlation between the number of punctures in relation to prostate volume and clinical outcomes [85, 106, 112–114].

Since then, many studies, including prospective randomized studies versus TURP, have been reported, and data are available on subjective improvements in symptoms and quality of life, and on objective improvements in urinary flow rates and PVR. In some studies, volume measurements gave outcomes on prostatic volume reduction, and pressure–flow studies on urodynamic improvement (Tables 130.3 and 130.4).

Several authors have used interstitial laser therapy for the treatment of BPH [9, 105–111]. Some have used the LITT light guide and transurethral application technique. Henkel *et al*. [108], Janetschek *et al*. [109], and Horninger *et al*. [110] employed LITT light guides as well, but inserted them exclusively from the perineum under TRUS guidance. The latter group used a three-dimensional imaging system [109, 110]. Handke *et al*., who also performed interstitial laser therapy transperineally, used another application system [78] specifically designed for interstitial treatment [111]. McNicholas *et al*. employed bare fibers, which they inserted under TRUS guidance, either transrectally into the side lobes or transurethrally for isolated median bar obstruction [17]. The vast majority of studies, however, were

	TUNA	34.8%
	WIT	27.5%
Zellner *et al*. (1994) [153]	ILC	20.3 cmH_2O

ILC, interstitial laser coagulation; TUNA, transurethral needle ablation; TURP, transurethral resection of the prostate; TVP, transurethral electrovaporization of the prostate; WIT, water-induced thermotherapy.

performed transurethrally using the 830-nm diode laser system [84, 89, 99, 116, 117, 120, 121, 124–126, 130, 132, 139, 140, 141, 143, 144, 150, 154].

Some studies were done on specific groups of BPH patients. Horninger *et al*. treated a selected group of 12 patients with large prostate glands (average volume 57 mL) [110]. Henkel *et al*. treated 38 high-risk patients and recorded an AUA score improvement of 26 to 9 after 6 months [108]. TRUS volumetry of the prostate showed a decrease in volume of 5–48%. The Qmax improved to over 15 mL/s in 50% of patients, and detrusor pressure normalized in 45% of patients. Bloch treated 28 outpatients, 14 of whom had chronic urinary retention [107]. Qmax improved from 5.0 to 14.3 mL/s (9.0–41.0 mL/s) and PVR from 152 to 54 mL on average [73].

Arai *et al*. treated 50 patients [106]. Although they performed only two to six fiber placements, they found that 80% of their patients were completely satisfied and had an AUA score improvement from 20.1 to 10.0; Qmax increased from 7.0 to 9.5 mL/s, and PVR decreased from 90 to 45 mL within 3 months. The prostate volume decreased from 33.5 to 27.5 mL. The retrospective analysis of these results leads to the interpretation that this was the first report on LV-ILC.

Complications

Specific complications of interstitial laser therapy are extremely rare. McNicholas *et al*. observed the only serious complication reported in the literature, which was a small bowel injury that occurred in one patient treated with a bare fiber that was inserted transrectally [47]. In theory, it is possible when using interstitial applicators and transurethral or perineal access that coagulation of the prostate capsule and adjacent organs may occur, but even if it does, this would probably not be of clinical significance in most cases. Coagulation of the neurovascular bundle and the rectum (the latter resulting in a fistula) could occur, but by avoiding extremely deep fiber placement, especially in a dorsal direction, this is highly unlikely. No reports on such events can be found in the literature.

In interstitial laser therapy the light applicators are placed into the tissue. Theoretically, they could break for one of two reasons: mechanical stress or overheating. A high degree of straining of the fiber can result in mechanical damage. In some types of applicators, damage can occur internally only and no parts can break off. If the tip were to break off, the stress point would always be outside the tissue at its surface. Therefore, the broken-off part of the applicator could easily be removed with forceps. Overheating because of the formation of char at the applicator tip could lead to a fiber breaking off inside the tissue. Most laser systems for interstitial therapy therefore have feedback systems that detect charring and switch the system off before the applicator can break. In the unlikely event of broken fiber fragments remaining in the tissue, they can be removed by electroresection, but in our experience and that of other groups this has never happened [37, 39, 40, 108, 110].

Other possible complications and side effects are not specific to interstitial laser therapy. Bleeding, if it occurs, is most often caused by mechanical trauma (e.g. of varicose veins on the urethral surface resulting from motion of the cystoscope). Minor bleeding from puncture sites is also possible. Bleeding usually stops within a short time without further treatment. To prevent clot retention, postoperative irrigation can be done for several hours. Significant bleeding from interstitial laser therapy is extremely rare; in all of the few reported cases it has been caused by the suprapubic catheter [12]. Unintentional infusion of irrigant or a significant TUR syndrome has not occurred in interstitial laser therapy [11, 15]. A mechanical perforation of the bladder or the prostate capsule is extremely unlikely to occur and has never been reported.

Frequently in the early postoperative period a transient increase in obstruction and a concomitant increase in obstructive symptoms occurs. Transient irritative symptoms such as urgency can also occur. These are

usually caused by edema but can also be associated with either secondary uncomplicated UTI or urethral necrosis. In the latter case, parts of the urethra are most likely coagulated as a result of placement of the applicator close to the urethra. This is often accompanied by tissue sloughing [14, 15]. No specific treatment of these conditions is required. Permanent incontinence has never been reported. The rate of UTI, which can occur because of postprocedure catheterization, can be kept low by simple antibiotic prophylaxis [14]. Significant UTI with fever, epididymitis, or prostatitis can occur after interstitial laser therapy with the same frequency as after any other transurethral procedure.

Urethral strictures or bladder neck strictures, which occurred in approximately 5% of patients in the first series, resulted from instruments and application technique that required further refinement and development [14, 15]. In the more recent series, the urethral strictures observed were recurrences of previously treated strictures [28, 29].

Patients' sexual function regarding libido and erection was not affected by interstitial laser therapy in the initial studies [14, 15]. A loss of prograde ejaculation is possible. In the first series of patients, 93.3% of the sexually active patients responding to a questionnaire indicated that they had retained normal ejaculation patterns [14–16]. Most authors either did not report on retrograde ejaculation or inability to ejaculate or did not encounter this complication [105, 107, 108, 110, 111]. Arai *et al*. found retrograde ejaculation in two of 50 patients [106]. In an international multicenter study, this complication was observed in 6% of patients [28]. If an additional bladder neck incision is performed, however, the rate of loss of prograde ejaculation can be higher [8, 29].

The serum concentration of PSA increases dramatically after interstitial laser therapy; within a short time, however, it returns to the pretreatment level [15]. A late recurrence of increased PSA level during follow-up must be looked at carefully. In conjunction with digital rectal examination, PSA can still be used for cancer screening.

CHAPTER 131

Electrosurgery of the Prostate: Improvements in Electrosurgical Unit, Transurethral Vaporization of the Prostate, and Bipolar Resection

Ranan DasGupta & Anup Patel
St Mary's Hospital (Imperial College NHS Healthcare Trust), London, UK

Historical development

The safe application of electrical energy to living organisms has underpinned many important surgical advances in the past two centuries. The first transurethral application of electricity to the human prostate was credited to the Italian, Enrico Bottini (1874); later, Wishard applied electrosurgical energy to the prostate under visual control, and Beer was the first to apply electrocautery under visual endoscopic control in a fluid environment. Hugh Hampton Young used a cautery punch device in 1911 to remove prostate tissue with a continuous flow instrument. William T. Bovie's pioneering design of an electrosurgical unit (ESU) combined a powerful cutting current and a damped coagulating current with separate footswitch control, which endures as the basis for modern electrosurgical generators.

In 1948, Iglesias de la Torre designed a spring mechanism in the resectoscope working element, allowing full control over the forward electrode excursion with a passive return excursion, while Baumrucker devised one that had exactly the opposite action. Endovisualization improved incrementally with Hopkins' rod–lens system, high-intensity external light sources, and video-camera miniaturization and high definition. Better antibiotics and anesthetic techniques, irrigant warming, and wider availability of blood transfusion, all helped to establish the place of the modern day transurethral resection of the prostate (TURP).

Impact of the electrosurgical unit and electrode configurations

Electrosurgical frequencies of greater than 100 000 Hz (radiofrequency range) avoid undesirable neuromuscular contractions and heat tissue by Ohmic resistance. Besides waveform, active electrode size and configuration affect current density and hence tissue effects. Rapidly reversing cyclical changes in molecular polarity lead to rapid intracellular water heating near the active electrode. This results in instantaneous steam production and cellular rupture, leaving a powdery residue and a tissue defect (the mechanism of monopolar electrosurgical tissue cutting). Irrigants must be nonconductive to localize current effects to the application site, while dissipating surface heat through conductive thermal transfer, and tissue circulation provides a deeper heat sink. The final tissue effects are governed by the maximum temperature achieved, the total time this temperature is sustained, and the rate of increase to the maximum temperature. Slow temperature rise times and/or low total thermal dose denature cellular proteins to desiccate cells, leading to coagulation necrosis. A rapid temperature increase greater than 100°C causes intracellular water to boil and, depending on power density, cells are desiccated, carbonized, or vaporized. Cutting and coagulation can also be produced by modifying electrical energy delivery, either by the source ESU or active electrode shape, or by modifying the surgical contact. For tissue cutting or vaporization, a voltage

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

high enough to produce an electrical arc from the active electrode to the tissue surface (i.e. peak >200 V) is required, remembering that arc formation is hampered by active electrode direct tissue contact during foot-pedal activation. This aspect of surgical technique, where the cut pedal is activated just before contact with the tissue to get the most efficient arcing, which is sufficient to form a plasma vapor to conduct subsequent current more efficiently, is of paramount importance when an active electrode of large surface area is used for a cutting effect, as in transurethral vaporization of the prostate (TUVP).

In contrast, the coagulation waveform differs from that used for cutting by being *damped* and *pulsed* to increase peak voltage for deeper tissue penetration and slower heat rise time, resulting in hemostasis through desiccation and coagulation below the tissue surface. Nevertheless, tissue cutting can still be achieved with this damped coagulation waveform if the power is increased, but this is self-limiting as there is rapid electrode and tissue surface carbonization, which insulates deeper tissue from further efficient vaporization. A better way to achieve simultaneous tissue vaporization and coagulation during transurethral surgery is to exploit the principles of cutting current density by *reducing contact size and surface*. Hence, for the same current in the cutting mode, a point electrode (or a thin-wire loop in endourology) provides excellent cutting, while a flat electrode with a larger surface area (or a barrel roller electrode) provides good surface coagulation. The unique combination of ridges or surface spikes (high-current density areas) with larger contact points (low-current density areas) in a single electrode allowed simultaneous tissue cutting and surface coagulation (transurethral vaporization of the prostate (TUEVP) using only a pure cutting current waveform for the first time. Balance is critical in surface and size design to avoid excessive desiccation leading to limited tissue removal and irritative symptoms. Increasing power simply results in greater charring, while running the electrode over the tissue to "clean off" the accumulated debris impairs tissue removal.

Variables affecting tissue removal during electrovaporization

Beyond electrode configuration, the electrode drag speed [1–3], reuse (diminishes the vaporization effect by 50%), and power curves of different generators are all critical [4, 5] Two clinical studies of photothermal interstitial thermometry during loop resection and electrovaporization with a variety of different electrodes and ESUs confirmed the findings that there was no excessive heating of the neurovascular bundles, while reaffirming the surface heat sink effect of continuous flow irrigation

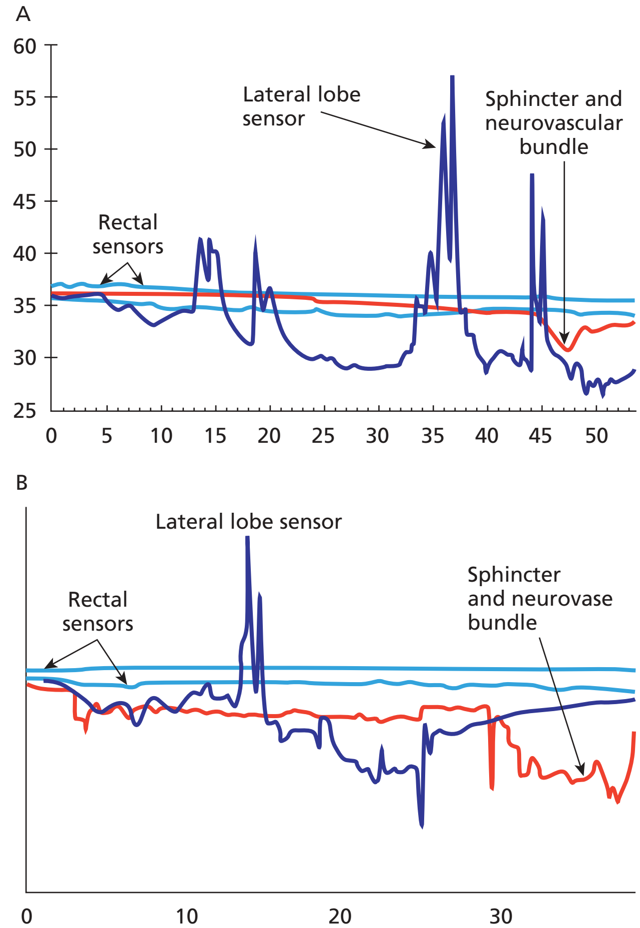

Figure 131.1 (A) Interstitial optical thermometry demonstrating temperature changes during transurethral resection of the prostate (TURP), and (B) during transurethral vaporization of the prostate (TUVP), confirming no unseen deep heating of vital structures, and protective cooling effect of continuous flow irrigation at the apex as the cavity is created.

(Figure 131.1) [6, 7]. Importantly, both sets of authors cautioned against prolonged applications of coagulating current, either at the level of the prostatic capsule or at the apex, for the higher peak voltage of the coagulating waveform facilitates deeper penetration and risks indirect and unseen neurovascular bundle damage at the apex or near posterior capsular perforations, particularly in small glands. In summary, these studies highlighted the fact that urologists must pay greater attention to many variables, such as electrode size and configuration, slower electrode excursion speed, and tissue contact pressure.

Improvements in electrosurgical unit technology

Contemporary ESUs have adopted integrated computer-controlled technology to monitor "real time" current

and voltage and autoregulate feedback according to the tissue impedance. Later generation ESUs either maintained constant *voltage* by automatically varying current and power (e.g. ERBE ICC 350; ERBE USE, Marietta, GA, USA), or constant *power* by automatically varying current and voltage output (e.g. Valleylab Force Fx™; Valleylab, Boulder, CO, USA). This helped to retain consistency of tissue interface effects within certain tolerances, allowing prostate electrovaporization at pure-cut settings below 200 W.

Some ESUs have incorporated special voltage-driven effects to improve tissue coagulation with loop and point electrodes. The ICC 350 unit from ERBE is one such device, and it has several incremental "high-cut" modes, which provide peak voltages between 400 and 700 V for deeper tissue penetration and coagulation. The combination of such units with loops that are thicker may produce marginally better hemostasis, although, so far in the published literature, this has not been significantly better than that obtained by an electrovaporization electrode coupled to an efficient generator and correct operative technique.

In an extension of the use of blended currents to reduce the bleeding associated with standard monopolar resection, in the mid 1990s, "coagulating cutting" was developed by Karl Storz (Tuttlingen, Germany), whereby phases with predominant cutting were alternated with shorter defined phases of coagulation. In clinical trials, however, the technique was disadvantaged by longer operative times related to a slower cutting speed due to a tissue drag effect during the phases of coagulation. To counteract this drawback, high-voltage pulses were introduced for the phases of coagulation, and coagulating intermittent cutting (CIC) came into existence. The output signal of the generator was a pulse-modulated sinusoidal wave of variable high amplitude voltage "tuned" for optimized cutting, but this time, due to sparking from the high-voltage pulses in a minority of cases, gas bubble formation increased and impeded the operator's vision. The last modification of the CIC generator deployed a controlled but variable (rather than fixed) pause between the cutting and coagulating pulses, each of which were of fairly constant voltage. In so doing, if power output decreased, the lag between the two pulses increased so that less power was delivered to the patient. However, once again, the energy load applied to the patient was higher, as with TUVP, and as before, no disadvantage was accrued [8].

A different strategy was used by Aesculap (Center Valley, PA, USA) with the Focus 640 ESU, to try to reduce excessive tissue charring during monopolar electrosurgical cutting with thin-wire electrodes. Its laboratory tests had apparently shown that the intensity of the monopolar electrode sparking, though well-defined at the moment of contact and at release of tissue contact, was variable through the duration of the cut itself. Consequently, it developed Microcut modes, which reduced the internal dosage voltage in such a way that a predetermined spark limit would not be exceeded if extensive sparking was detected. Thus, the Microcut modes limited spark intensity and minimized effective power at the electrode for an excellent cutting effect, while avoiding collateral tissue damage.

Bipolar prostate electrosurgery

Technology

This technology updated and revitalized a technique that was tried in the early decades of the last century. What then was the attraction of such technology over standard monopolar loop resection? The IEC60601-2-2 definition of bipolar is that it is a method of applying high-frequency output current to a patient via multiple-pole active electrodes. It permitted electrosurgical tissue cutting in conductive saline, offering urologists the possibility of using more endoscopic resection time and tackling larger glands without risking morbidity from water absorption and TUR syndrome.

As with monopolar cutting, the generator must initially produce a momentary high-energy spike to initiate a plasma vapor layer ionized in the form of a nonequilibrium plasma, where plasma ions and electrons are responsible for current flow. Unlike monopolar surgery, the current does not arc to the tissue and a return electrode with a large surface is not required. Instead, both active and return electrodes are in close proximity, separated by an insulator. The electron emission from the smaller active electrode vaporizes the adjacent liquid to form a thin gas layer (plasma pocket) that grows to form a larger bubble containing energetic species that can dissociate both water and organic molecules (Figure 131.2). It is likely that the thermal effect probably occurs at much lower temperatures (<70°C) compared to that with monopolar surgery (300–400°C).

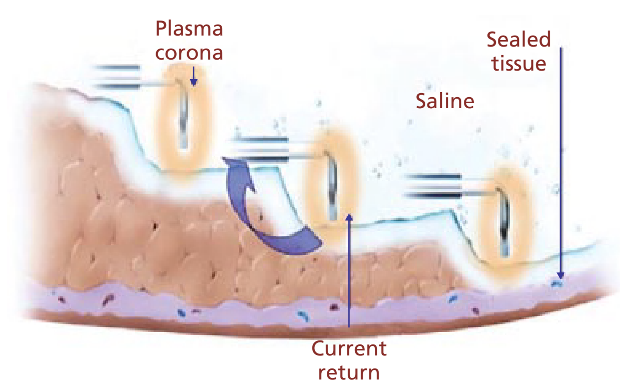

Figure 131.2 Formation of plasma pocket around active electrode and return pathway of current.

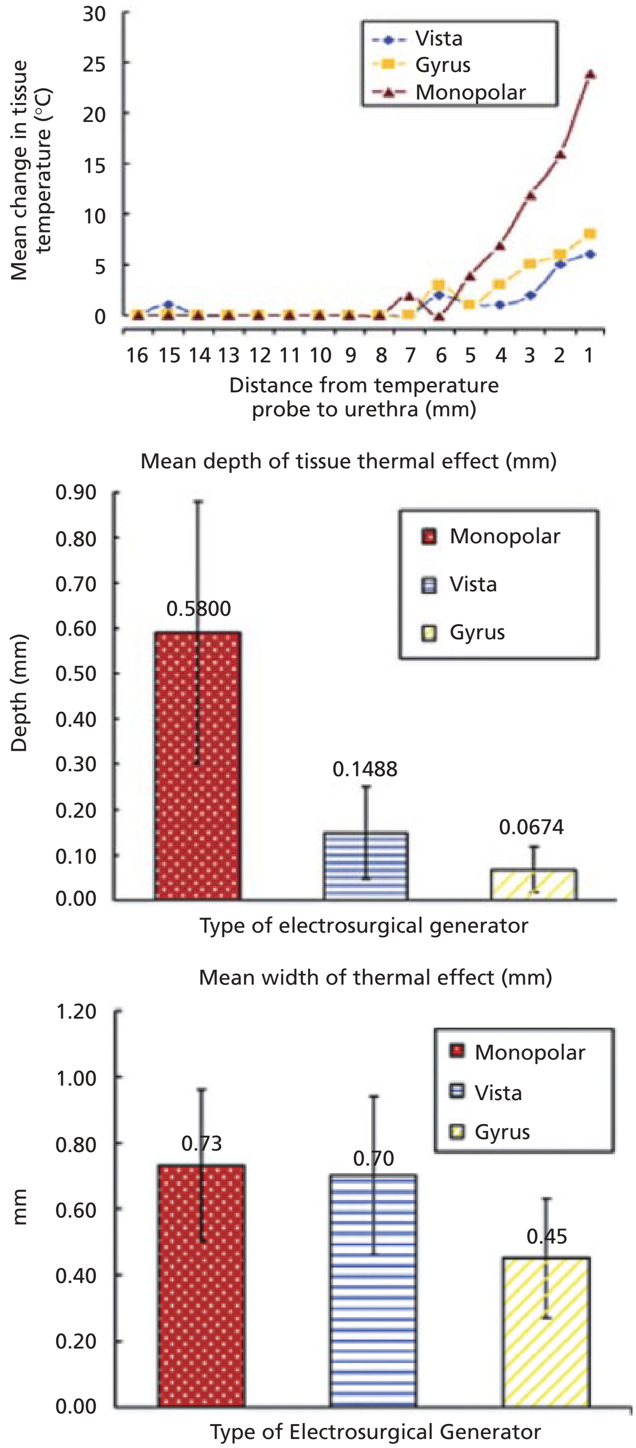

Figure 131.3 Thermal penetration in tissue comparing monopolar and bipolar or PK systems (reproduced from Ko *et al.* [9], with permission).

All bipolar technologies use radiofrequency (RF) energy output from specialized ESUs [320–450 kHz for Gyrus PlasmaKinetic (Gyrus Medical, Maple Grove, MN, USA; now acquired by Olympus, Tokyo, Japan), 100 kHz square wave for the now discontinued Vista Coblation system (ACMI Corporation, Southborough, MA, USA) and 350 kHz for the Olympus SurgMaster generator . A recent study by Ko *et al*. compared the heating effect and histopathologic effect of bipolar (Gyrus PlasmaKinetic and Vista) versus monopolar TURP in a canine model (Figure 131.3); they showed significantly less heating (including near the neurovascular bundle) and less evidence of thermal damage with bipolar compared to monopolar diathermy [9]. The energy passes down the active electrode, through the plasma pocket and thence through the conductive solution to the tissue bed before returning to the thicker return, and then finally returning to ground through the active cord. Furthermore, the combination of low operating frequency and low voltage in bipolar prostate electrosurgery should also eliminate the possibility of interference with all types of cardiac pacemakers. Differences in arrangement of active and passive electrodes allow distinction between devices: whether two loops (parallel or opposite), using the distal end of the resection loop, or using the working element of the resection shaft.

The common challenges faced by each of the systems are to reliably establish a cutting plasma corona preferentially at the distal active electrode, to minimize the time from foot-switch activation to plasma production (i.e. instantaneous fire-up), to maintain this under all cutting conditions, and to provide adequate hemostasis from both cut and coagulation modes.

The configuration and size of the active electrode for prostate resection and incision is unique for each of the commercially available systems (Figure 131.4). Although there are certain basic similarities (e.g. active electrode slightly thinner and separated from the thicker return electrode component by an insulator), there are differences in resectoscope size, and design of the electrode housing and coupling to the active and return cords. At the moment of fire-up by foot-pedal activation, if the activated component of the bipolar electrode is not in contact with the tissue, if the gap is too wide, or if there is insufficient power, current flow is simply dissipated by the large volume of electrolyte solution in a full bladder, and there is no effect. On the other hand, if the power/voltage spike is not high enough both to form and maintain the plasma vapor pocket, stuttered cutting will result, depending on the quality of tissue contact.

Gyrus-ACMI

As a result of these challenges, the initial PlasmaKinetic (PK) Gyrus system, which was the first to encounter some of the above difficulties, has been modified in recent years, culminating in the Gyrus SuperPulse® Generator. This newer device is preconfigured for

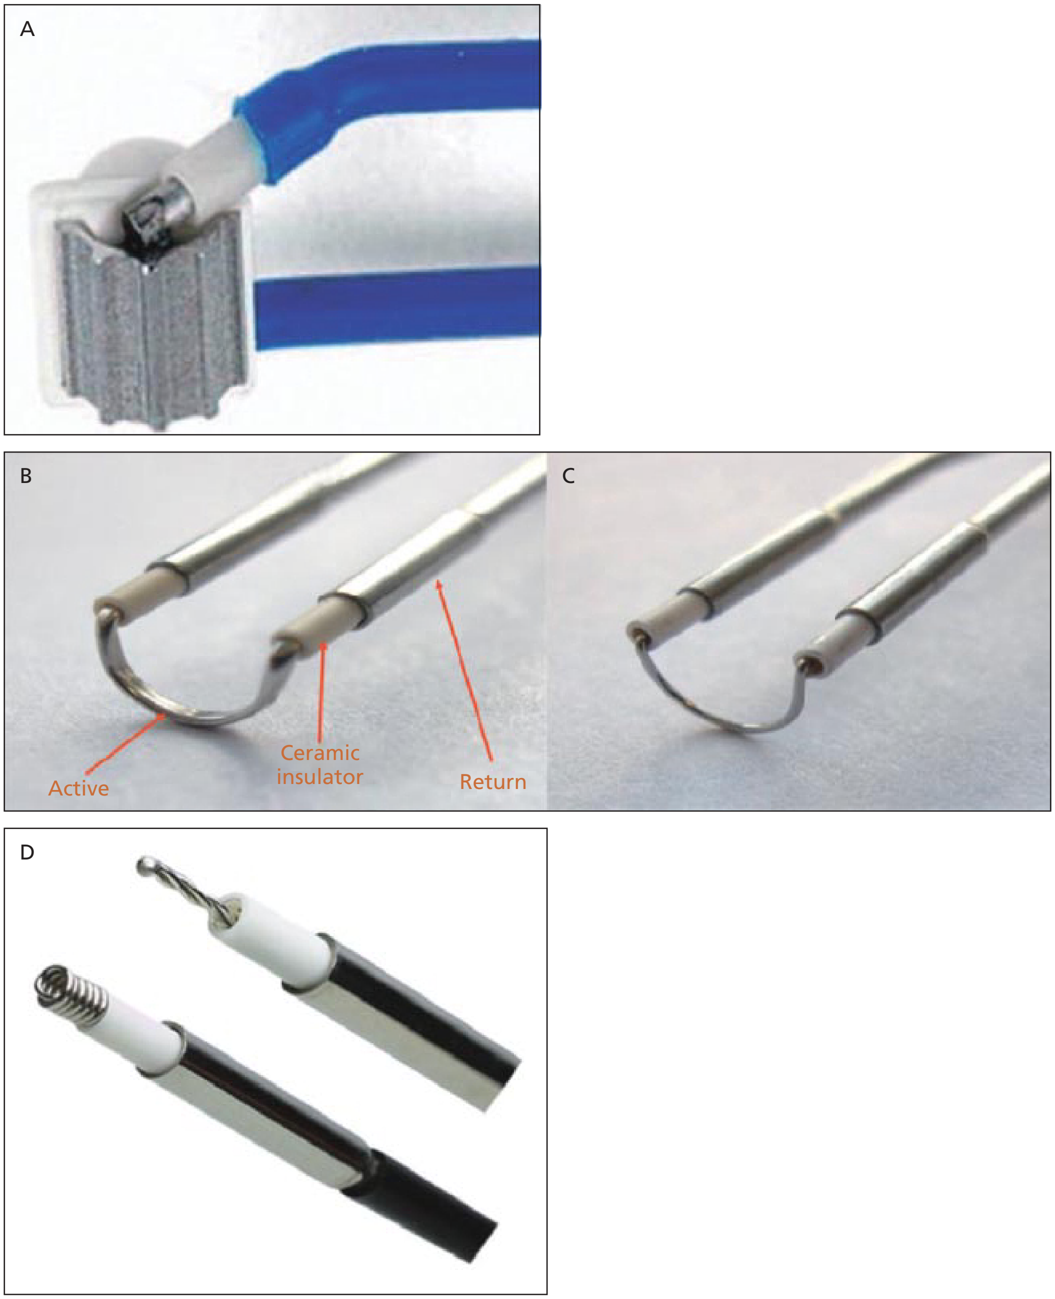

Figure 131.4 Bipolar electrode configurations of (A) Plasma V vaporization electrode (courtesy of Gyrus Medical, Maple Grove, MN, USA); (B) SuperSect thick and (C) SuperLoop thin resecting loops (courtesy of Gyrus Medical); (D) PlasmaCise thick and thin incision electrodes (courtesy of Gyrus Medical); (E) Vista Coblation resecting double loop (courtesy of ACMI Corporation, Southborough, MA, USA); (F) SurgMaster (courtesy of Olympus, Tokyo, Japan), single resecting loops (large, medium, small, and angled) and other electrodes; (G) Storz double resecting loop (© courtesy of Karl Storz, Tuttlingen, Germany); (H) Wolf bipolar electrodes (courtesy of Richard Wolf, Knittlingen, Germany).

maximal allowable current under low impedance conditions. However, the surgeon is able to choose between two sets of cut voltages, which are preset (represented by SP1 and SP2). The SuperPulse Generator is designed to recognize the active electrode and offers default settings that are optimal for a range of conditions at the tip [e.g. SP2 160, corresponding to a maximum voltage of 307 volts root mean square (Vrms) sinusoidal (434-V peak) and 160-W maximum average power]. While the original Gyrus device had the active and return electrodes on the same axis, separated by a ceramic insulator, the subsequent Plasmasect and PK systems retained the coaxial principle but redesigned the tissue contact points into loops, thus allowing resection of tissue.

Figure 131.4 *Continued*

The SuperPulse Generator contains an energy reservoir facility in the form of a bank of internal capacitors. In this way, there is provision of sufficient voltage for both instant fire-up at the start of each cut and for power ride-through under challenging conditions of impedance. In this way, this manufacturer has resolved the problems of stuttered cutting that occurred with the previous generation of the device. The reservoir bank is quickly precharged before foot-pedal RF voltage initiation by the surgeon. Tests have shown that under high-flow and cold saline conditions, more power than normal is required to initiate and maintain plasma conditions at the active electrode tip. The capacitor reservoir can provide up to 4000 W of power for short periods (~10 ms), but only if the tip impedance is low enough.

At baseline, before RF voltage application, the impedance differential between bipolar active and return electrodes is between 23 and 60 ohm, depending on the saline temperature and the proximity of the active electrode to the tissue bed. At high power (4000 W) and low impedance (23 ohm), a voltage of close to 300 Vrms can be sustained by the SuperPulse Generator for long enough to allow saline immediately surrounding the active loop to be actively heated and reach boiling point

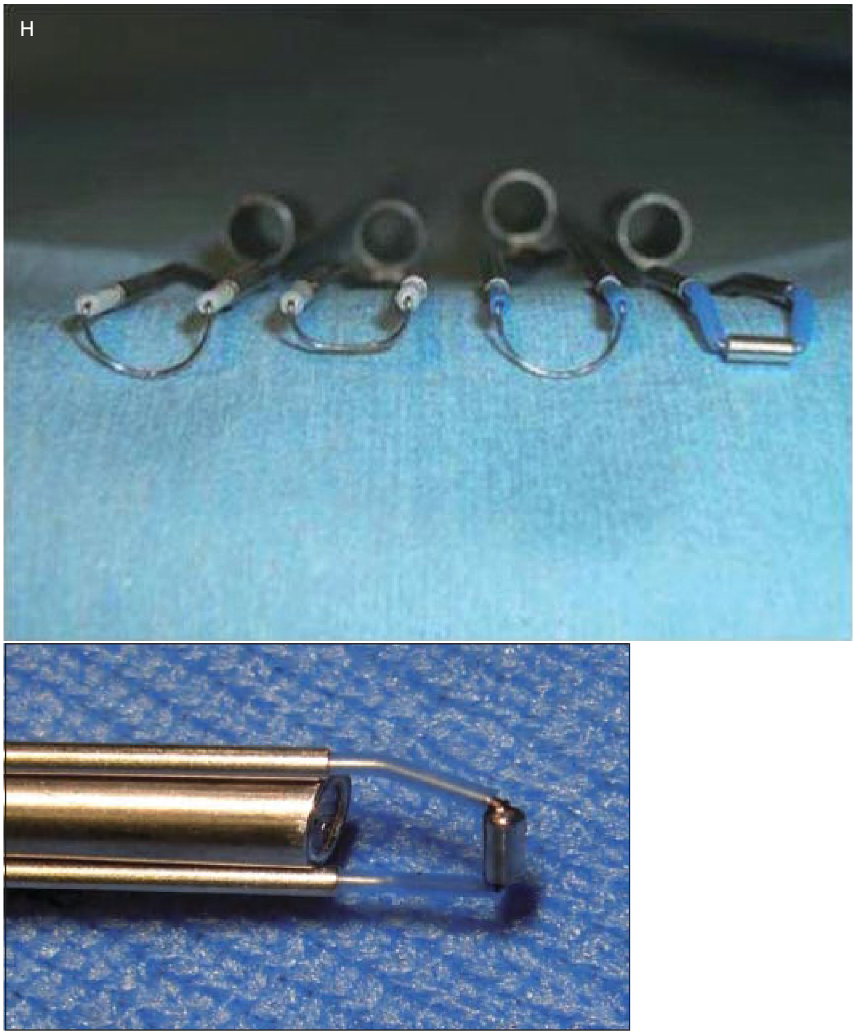

Figure 131.4 *Continued*

in a few milliseconds. This phenomenon is due to current crowding at the reduced surface area of this part of the active electrode, and it creates a nonequilibrium vapor pocket containing charged sodium ions.

Clinically, there is a precision tissue effect with minimal collateral damage, as the charged ions have only a short estimated range of 50–100 µm of penetration. The extent of the collateral tissue damage depends on resistive heating caused by any current flowing through the tissue, and by limited thermal transfer from the electrode sources. The end result is excellent localized cutting, with little in the way of the burnt smell traditionally associated with monopolar cutting. The depth of the surface coagulation is determined principally by the electrode configuration and by the system design, as well as by the technique used by the operator (time and pressure of contact). Coagulation has to take place with this technology at low peak voltage (in direct contrast to monopolar coagulation: 80–100 V for the PK system and 65–115 V for the Vista system), as higher peak voltages convert the liquid into a gaseous phase of higher impedance. This, in turn, changes impedance from a resistive to a capacitative mode, which reduces energy flow, reduces dissipated heat, and limits the final coagulation effect. Hence, longer contact times may be needed.

There are several electrodes available with the Gyrus system, including the SuperSect® Loop (with a wide surface area that helps to seal bleeding vessels, making it ideal for prostate resection) and the SuperLoop® (thinner, more traditional loop, making it ideal for bladder tumor resection); also, there are the PlasmaCut® and PlasmaCise® electrodes that have braided tips for treatment of urethral strictures and bladder neck stenoses. The resectoscope and electrode fittings are shown in Figure 131.5.

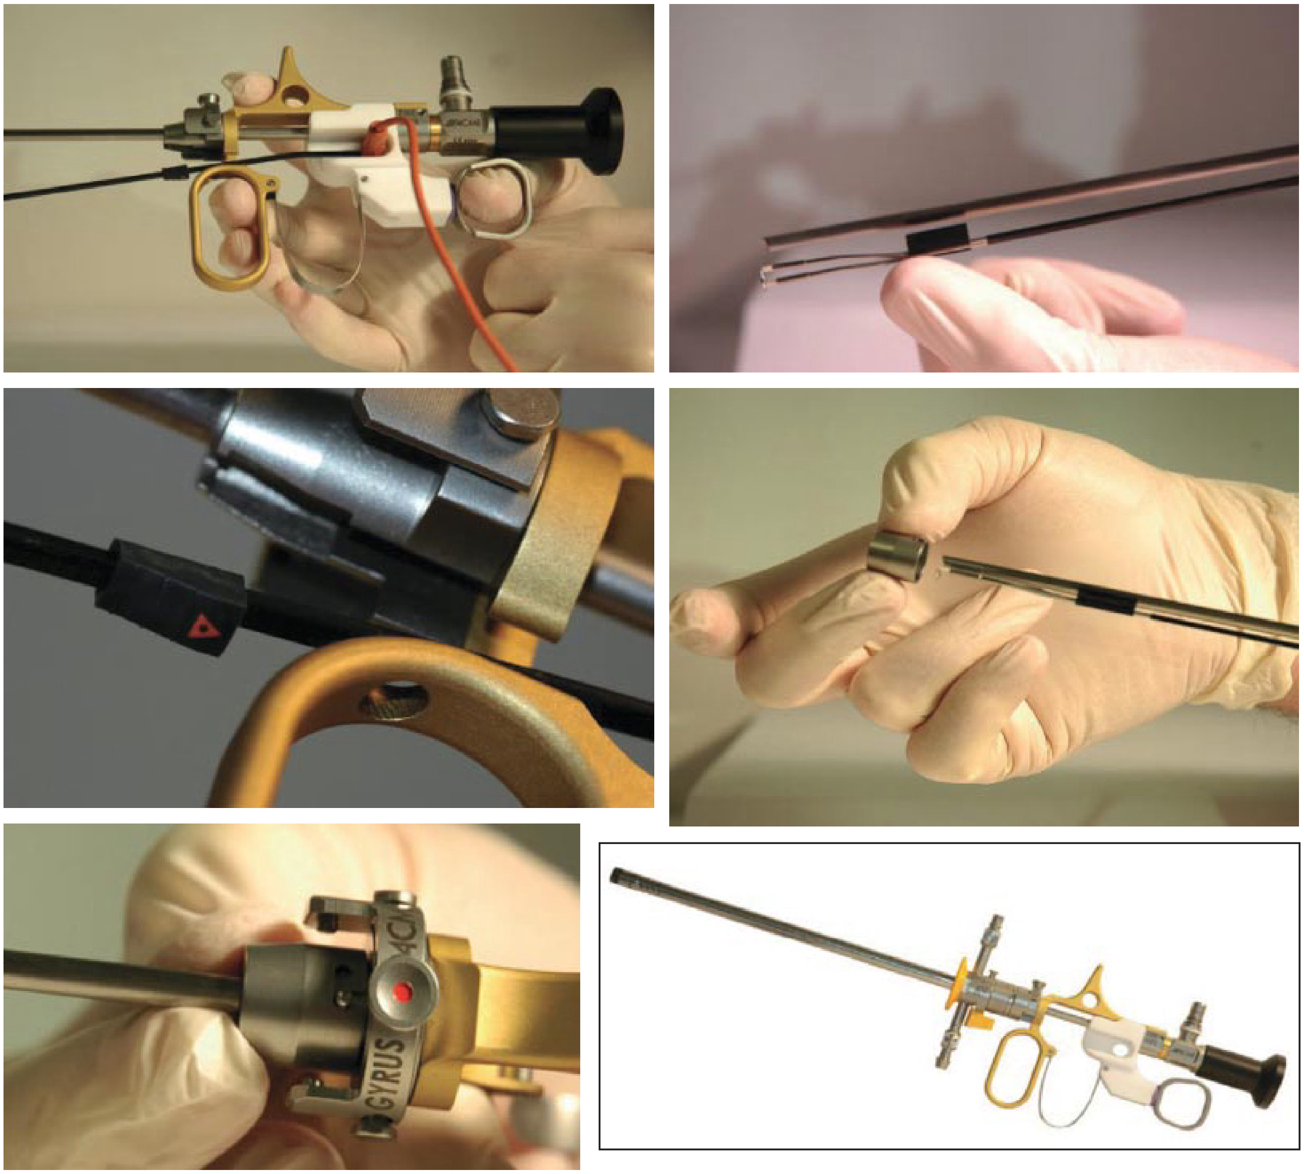

Figure 131.5 Electrodes and fitting of the Gyrus-ACMI resectoscope loop (courtesy of Gyrus Medical).

Olympus

The SurgMaster system uses a loop design similar to those developed by Gyrus, but the loops are of a slightly smaller diameter, thin-wire design, and separated by yellow insulating material from a thicker more bulbous return end. The resectoscope itself is 26F in size and has a working length of 194 mm. This design also permits current crowding at the thinner active loop to allow the plasma pockets to be formed. The current reaches the active portion of the loop from the generator through the white plastic housing in the bottom of the working element, while the return current flows through the return portion of the electrode in contact with the working element and then back to earth through a lead connected to the working element handle. Hence, part of the telescope housing of the working element is specially insulated to make it fit for this purpose, without compromising patient or operator safety by return current leakage. At the resectoscope tip, the electrode and telescope are separated from the metallic outer sheath by insulating material (Figure 131.6). The SurgMaster generator in the "TURis" (transurethral resection in saline) mode allows saline resection through two cutting modes (pure and blend with maximum power output of 320 W) and coagulation through two modes designated Coag. 1 (maximum 200 W) and Coag. 2 (maximum 80 W), though only in combination with the SurgMaster resectoscope. It also has a capability to produce a monopolar output for standard surgical and endosurgical use.

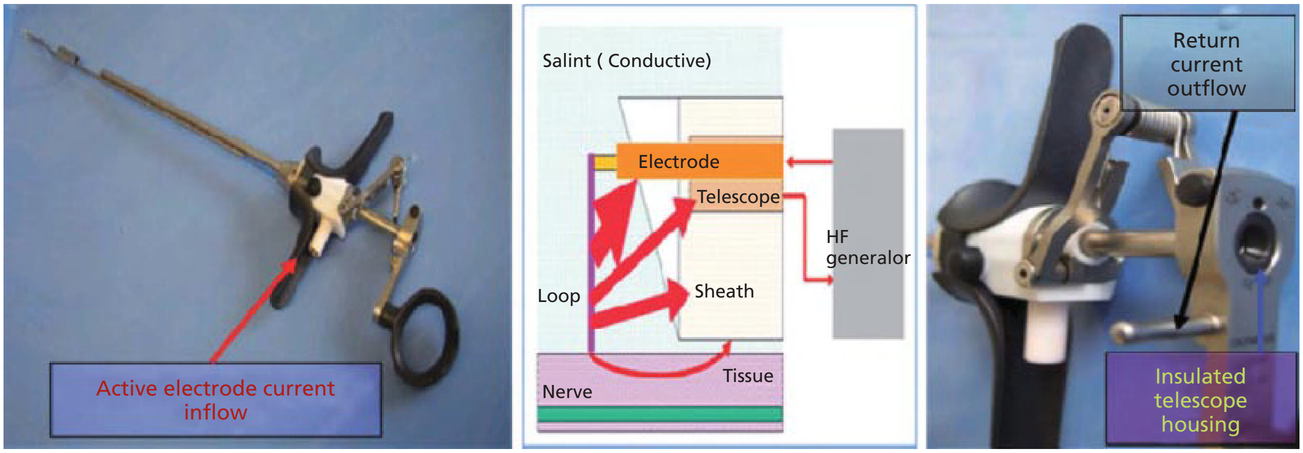

Figure 131.6 Design of active loop and working element for SurgMaster® resectoscope (courtesy of Olympus, Tokyo, Japan). HF, high frequency.

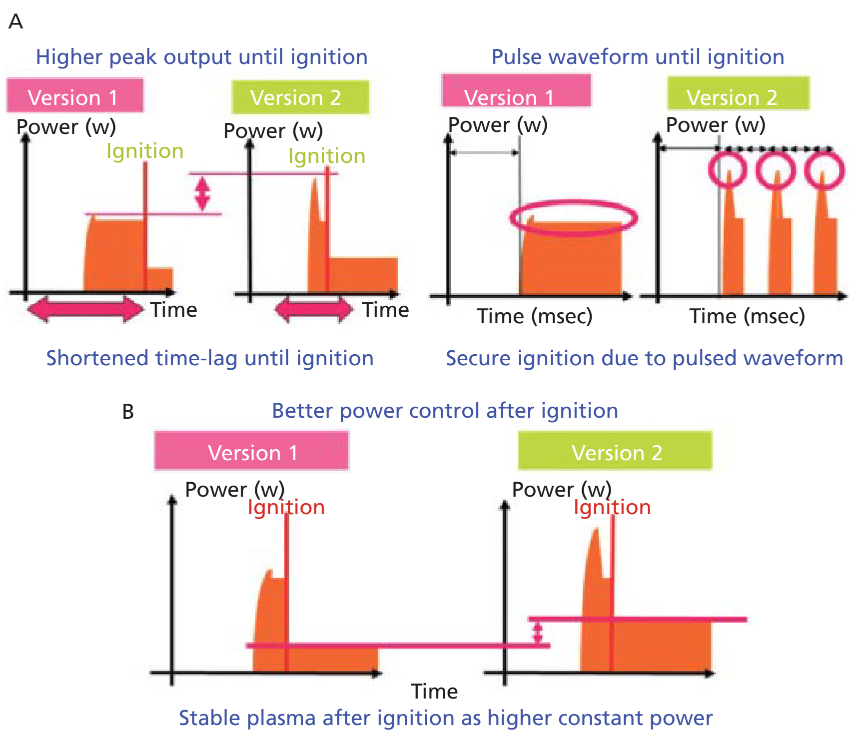

Figure 131.7 (A, B) TURis SurgMaster® second-generation generator modifications (courtesy of Olympus).

In the TURis system the active electrode is in the resection loop, while the return electrode is in the working element of the resectoscope; this has cost implications, since whereas the Gyrus coaxial electrode and ceramic insulator resulted in a PK loop costing approximately US$300, the corresponding cost for a TURis loop was US$60 [10]. The device may be set at 280 W for cutting and 100 W for coagulation. The second-generation of TURis devices can be compared to the first-generation devices in terms of higher peak output until ignition (but now with a shortened time lag until ignition), as well as a pulsed waveform output until ignition (Figure 131.7A); after ignition, the second-generation devices then also produce a more stable plasma, with higher constant power (Figure 131.7B). It is not known yet whether these changes in generator design will ultimately wear out thin loops quicker with prolonged use in larger glands.

Another recent modification is the new electrode designs, including a mushroom-shaped electrode

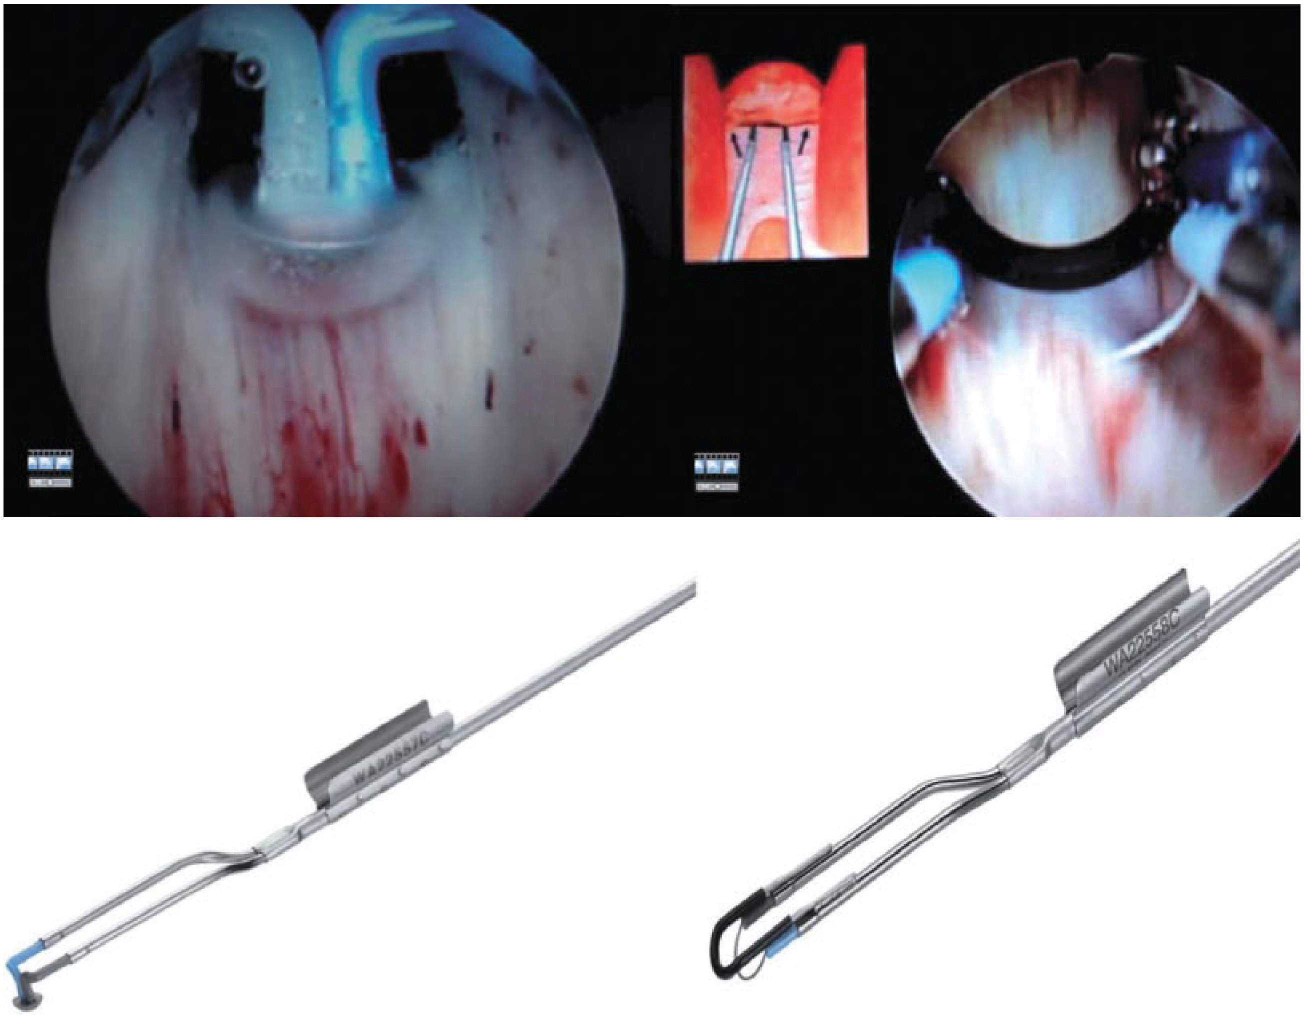

Figure 131.8 Mushroom-shaped button electrode and double-loop electrode for resection–enucleation (courtesy of Olympus, Tokyo, Japan).

(Figure 131.8), which permits vaporization of the prostate, with heat penetration up to a depth of 0.20 mm.

Enucleation of the prostate is now also feasible with the new double-loop electrode design (Figure 131.8), but unfortunately, this has the same downside as its laser equivalents in that it needs to be combined with adequate morcellation, which is still the main limiting factor for any enucleation technique.

Karl Storz

The Storz bipolar resection system was the third of the four commercially available systems. It consists of a classical double loop with a 5-mm diameter thin-wire active component and a flat thick bow loop bent in the opposite direction, which is the return component, with both loops mounted on the same axis of a dedicated resectoscope. It was found that a power setting of over 300 W was needed for *in vivo* cutting (compared to monopolar cutting, which can happen at 80 W). Furthermore, there could be a delay of almost 1 s until the loop became submerged in the tissue and reliable cutting occurred. Bleeding rates were lower than for monopolar diathermy, and the coagulation zone slightly deeper for the bipolar device. Electrical recordings suggested that using the standard generator, the 0.8-s delay in onset of bipolar cutting and inconsistency of cutting quality (as with many of its predecessors) were due to the time taken for the high current output at low impedance to produce the vapor pocket, and this, in turn, was critically dependent on electrode configuration, and generator design and function. Measurements taken during a single bipolar cut, which show the delay to actual cutting, followed by voltages of up to 450 V and

power of up to 475 W under varying impedance conditions during actual cutting, support the need for a dedicated generator design with such devices, for it is likely that systems that do have difficulty initiating fire-up will have greater thermal spread in tissue at the point of RF initiation because the surgeon cannot move the loop until the vapor pocket and plasma have been (slowly) established [11].

Since this first-generation system, a second-generation system has been released by this manufacturer, extending the range of electrodes (Figure 131.9), which have been slightly reduced in size compared to the first generation. The Autocon®II 400 ESU has in addition to both standard bipolar and unipolar output modes, a newly added Resection box connected in series for saline bipolar procedures. It is designed to enable more effective power delivery in low impedance (saline) conditions by the addition of "Saline-C-Cut ++" and "Saline-Coag ++" modes. This system and electrodes are yet to be studied in the clinical setting.

Richard Wolf

The Wolf S(a)-Line system (Figure 131.10) (Richard Wolf, Knittlingen, Germany) was the last to appear commercially and has similarities in construction to the system from Olympus, with a compatible electrosurgical unit. There are sparse peer-reviewed published clinical data on this system at the time of writing.

Technique

Although there should be no problem with TUR syndrome with bipolar loop resection, urologists must adhere to the principle that there is no place for complacency as far as surgical technique is concerned. Hypervolemia and hypothermia from cold saline absorption through the resection fossa can still occur, leading to heart failure in elderly patients with cardiac comorbidity, so irrigant should still be warmed before use and the operator should empty the bladder periodically of accumulated irrigant (since inflow is usually greater than outflow, even with continuous flow resectoscope systems). Furthermore, regular emptying of the bladder helps to better reveal bleeding points so that they could be controlled in a timely fashion.

With regard to handling the resectoscope, Rassweiller *et al*. compared the standard monopolar device with the ACMI bipolar, Gyrus PK and Storz bipolar instruments, in terms of ease of connecting the electrode, initiation of cut, coagulation, and lifetime of the loop, and showed them to be broadly similar (Table 131.1) [12].

If, as is suggested by the studies of Wendt-Nordahl *et al.* [11], bipolar coagulation is shallower than monopolar coagulation with the Vista system, then it is likely that the incidence and duration of postoperative irritative symptoms (which are usually the result of an excessively coagulated tissue bed and delayed sloughing of this tissue, as was seen with Nd:YAG laser therapies in the past) could be reduced and shortened. Evidence to support this contention was provided by the study of Singh *et al.*, who performed a randomized controlled trial in 60 men comparing the Vista bipolar resection system versus a regular monopolar loop [13]. No difference was found in clinical outcome parameters, but irritative symptoms of postoperative dysuria in particular were less common with bipolar loop resection. The key remains whether all systems have a similar action on the tissue bed with regards to depth, given the design and generator variations from one system to another.

Outcomes of bipolar transurethral resection of the prostate

A recent meta-analysis of 16 RCTs comparing bipolar (704 patients) with monopolar TURP (702 patients, total 1406 patients) by Mamoulakis *et al*. has highlighted the challenge of analyzing heterogeneous data from different centers [14]. The studies included 10 PK trials, four TURis trials, and two Vista trials. The largest studies were from Turkey (120 in each arm [15]) and Belgium (approximately 120 in each arm [16]). Apart from the 4-year update on a prospective randomized RCT described by Autorino *et al*. [17], the length of follow-up from the other trials was rather limited, at a maximum of only 1 year.

Nevertheless, there appeared to be no statistically significant differences between bipolar and monopolar TURP in terms of short-term efficacy. With regard to safety, a number of factors were analyzed, including the incidence of TUR syndrome. Although the individual trials did not show a significant difference, a total of 13 cases of TUR syndrome were reported with monopolar TURP versus none with bipolar TURP. The authors proposed that 50 patients with bipolar TURP would need to be treated for there to be one less TUR syndrome episode, and 20 patients to prevent one less clot retention episode.

Also, there appeared to be no major difference in hemoglobin drop after either procedure, which seemed counterintuitive to the argument that bipolar TURP gives better hemostasis. Interestingly, in the accompanying editorial, it was pointed out by Reich that in his narrative experience (a view he felt was shared) that there was no tangible difference in hemostasis with this technique, possibly confirming the findings of the meta-analysis [18]. At the time of writing, a Swedish randomized study by Fagerstrom *et al.* of 202 patients,

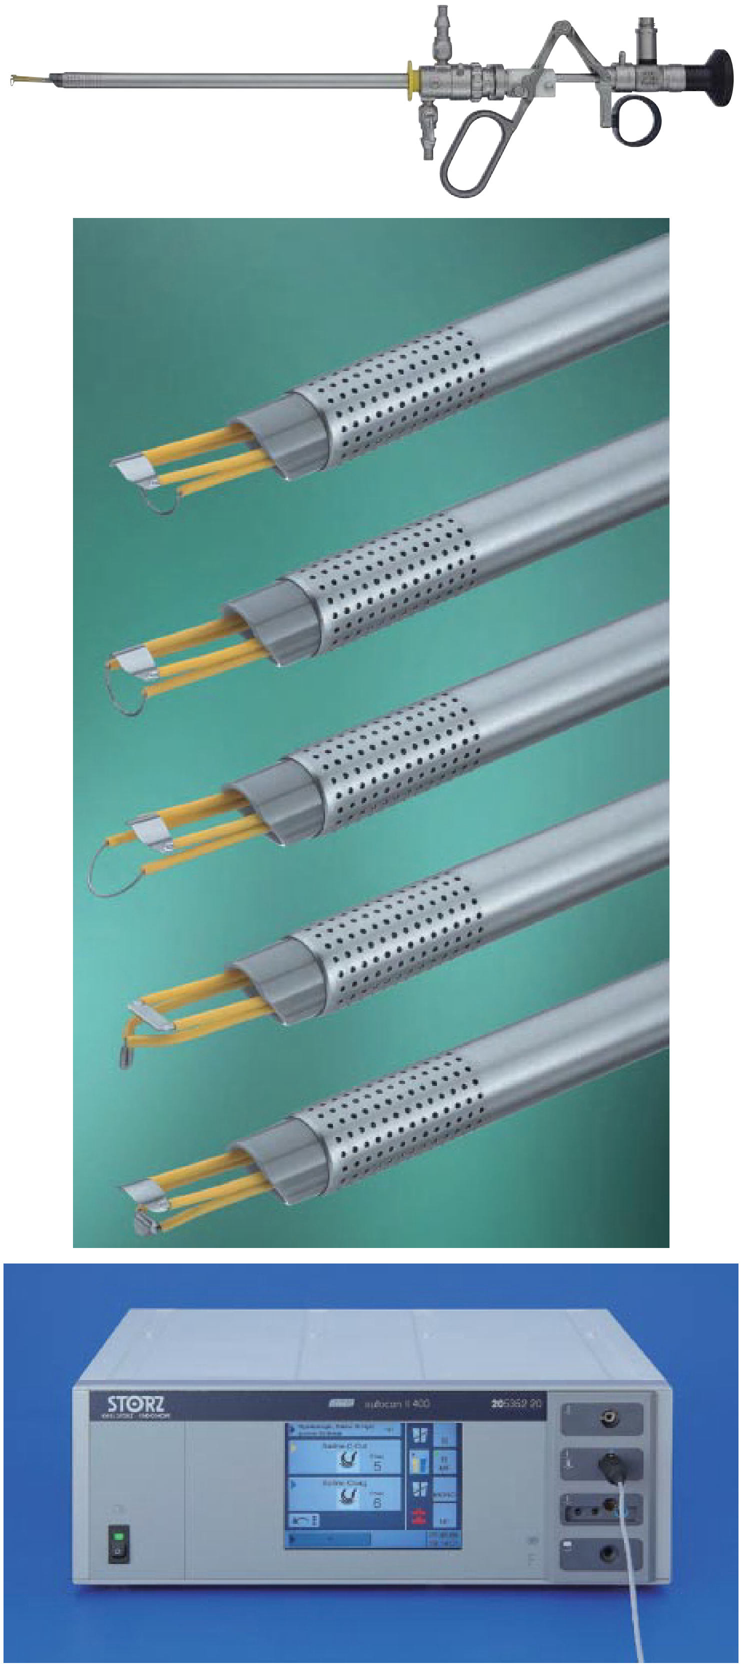

Figure 131.9 Storz bipolar resection system: resectoscope, second-generation electrodes for resecting prostate and bladder, incision and vaporization, and Autocon® II 400 ESU Bipolar Saline Resection Box (© 2010 Photos courtesy of KARL STORZ Endoscopy-America, Inc.).

Figure 131.10 Wolf S(a)-Line bipolar resectoscope working element design (courtesy of Richard Wolf).

Table 131.1 Handling of bipolar resectoscopes compared to the monopolar device (modified from Rassweiller *et al*. [12]).

Feature	TURP mono	Gyrus PK	Storz bipolar	Olympus TURis
Size (F) of resectoscope	24	26	24	24
Connecting electrode	Easy	Easy	Easy	Easy
Starting cut	+++	+++	+++	+++
Resection speed	+++	+++	+++	+++
Fine resection	+++	++	+++	++
Coagulation	+++	+++	+++	+++
Loop lifetime	+++	+++	++	+++

undergoing bipolar TURis or monopolar TURP, reported a 34% lower blood loss (235 vs 350 mL, $P < .001$) in the bipolar arm [19].

The rate of postoperative urethral stricture was also reviewed in the meta-analysis of Mamoulakis *et al*. [14]. While there was no statistically significant difference between monopolar TURP and either Vista, Gyrus or TURis procedures, single studies have mentioned differences. For example, Ho *et al*. reported three urethral strictures in 48 patients in the bipolar arm of TURis compared to one in 52 patients in the monopolar arm [10]. It has been speculated that this may reflect the outer sheath of the resectoscope acting as the return electrode, thus theoretically increasing urethral mucosal damage from localized small contact points. The theoretically possible localized current pathways from bipolar/quasi-bipolar energy, particularly if they are altered by uneven application or distribution of lubricant gel on the instrument surface, are illustrated in Figure 131.11, as postulated by Faul and Fastenmeier [20]. A large series of 1000 patients undergoing TURis procedures (both prostate resections and bladder tumor resections) reported a urethral stricture rate of 2.9% after bipolar TURP [21]. This compares favorably with published rates for monopolar TURP; interestingly, Puppo *et al*. mentioned performing urethrotomy prior to resection in cases "with an inappropriate relationship between the size of the instrument and the diameter of the external urethral meatus" [21]. An earlier study found a lower rate of urethral stricture at up to 6 months in TURP patients undergoing an initial Otis urethrotomy compared to no urethrotomy [22]. Other factors that may contribute to stricture formation include the resectoscope diameter (e.g. 27F for Gyrus PK), size and material of catheters, and higher ablative energy used, though overall there appears to be no significant difference between bipolar/quasi-bipolar and standard TURP.

Similarly, no difference was reported in the risk of postoperative acute retention in the meta-analysis [14]. The duration of postoperative catheterization varied between the studies, but this actually reflects variation in local policy (not protocol driven) and is therefore not necessarily a valid independent endpoint for comparisons. Retrograde ejaculation rates were similar for both monopolar and bipolar technology, as may be expected. A randomized controlled trial to assess incidence of postoperative erectile dysfunction is awaited, grouping small, medium, and large glands separately for analysis, since bipolar energy would theoretically produce less transmission of heat energy, thereby causing less damage to the adjacent nerve bundle.

While it is possibly most relevant to compare the use of these cauterization techniques, it would also be topical to compare bipolar TURP with the other modality proposed to produce less blood loss, namely laser techniques. Several laser technologies are now available, but broadly speaking, there are ablative techniques [e.g. KTP (GreenLight™) or diode] or ablative/enucleation/resection techniques (holmium or thulium). With the advent of the mushroom (or button) electrodes that allow vaporization using TURis, a true comparison with an ablative laser is now feasible. Similarly, enucleation techniques can now be compared between bipolar resection and the holmium laser, with morcellation techniques now available. Some argue that future studies

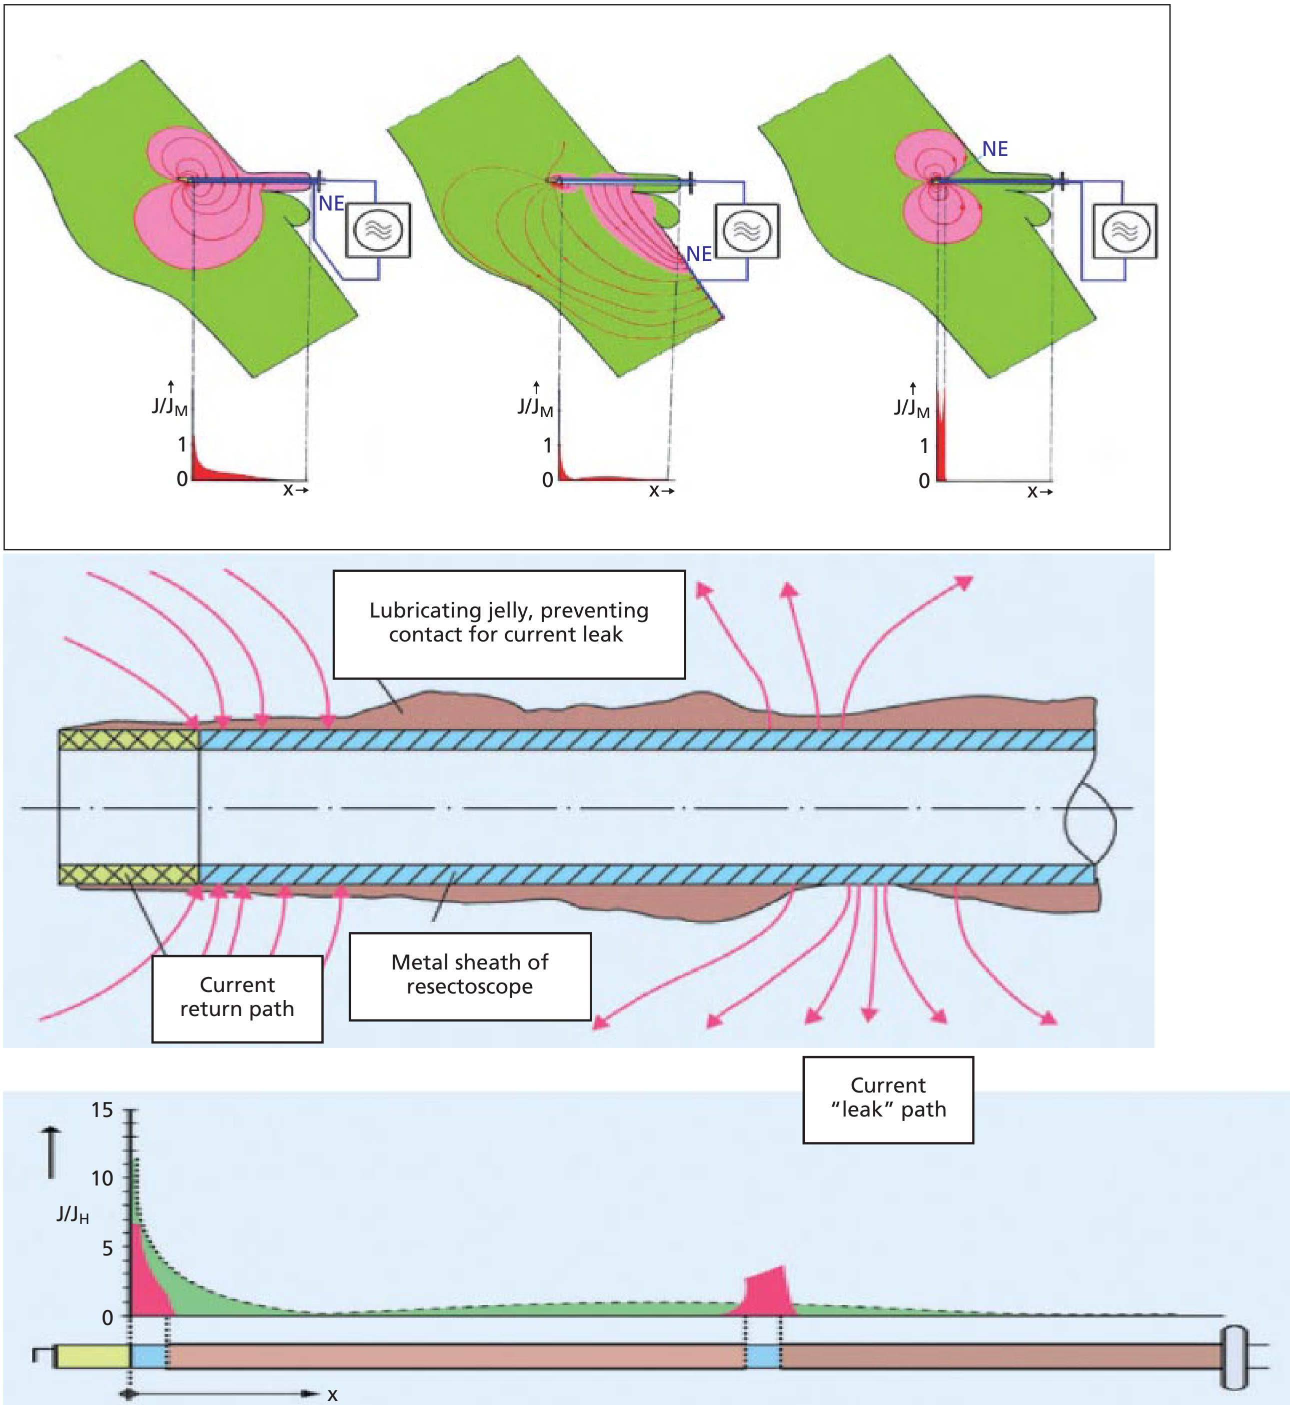

Figure 131.11 Quasi-bipolar, monopolar, and bipolar respective possible electric current flows and possible differences in urethral contact with resectoscope depending on surface lubricant inequalities [20]. The areas with inadequate lubricant cover theoretically could permit conduction of current from small localized contact areas away from the resectoscope sheath to the adjacent urethra, possibly increasing the chance of thermal damage to adjacent structures. (From Faul and Fastenmeier [20], with permission.)

should compare bipolar with laser technology (rather than with monopolar), and multicenter trials are eagerly awaited in these areas.

Training and morbidity

Bipolar TURP should allow more time for teaching and training urology residents in how to resect prostatic adenomatous tissue without compromising patient safety, for all preliminary studies have shown the risk of hyponatremia to be uniformly low. This is a welcome advantage for the novice trainee, freed of the shackles of time constraint to a large degree, both for the resection phase and also for the coagulation phase of the operation. This is particularly important when the use of TURP has been declining, and a large proportion of patients requiring surgery are either in acute or chronic retention or have large vascular glands (as combination medical therapy with alpha-blockers and cytoreductive 5-α reductase enzyme inhibitors does not have widespread penetration into routine clinical practice due to cost).

With regard to the technique, only minor changes are needed, and for urologists already proficient in performing monopolar TURP, as bipolar systems are almost identical with regard to equipment, the learning curve should be almost negligible. At this time, it is not known whether the risk of capsular perforation and subsequent impotence will be reduced until this issue is formally studied. Hemostasis seems to be slightly improved at the resected tissue surface, but deep coagulation is limited, and care must still be taken to avoid opening large venous sinusoids.

One of the concerns that exists for many transurethral bipolar resection systems, as with monopolar electrosurgery, is the potential for urethral and bladder neck stricture formation postoperatively. Although reports on bladder neck strictures for the bipolar systems are sparse, the incidence of urethral strictures in the study by Tefekli *et al.* at 6.1% (vs 2.1% for the monopolar TURP arm) is of concern [23]. Etiologically, there are many possible reasons for the higher stricture rate in this study and that by Ho *et al*. [10]. These include larger resectoscope diameter (27F), especially if the urethra is not adequately predilated before passage of the resectoscope, higher incident power (even if in short bursts), electrode re-use, and if a larger prostate is tackled or one is tackled by a relative novice, a long operating time. Of interest is the paper from Morishita *et al.*, which, in 1992, indicated that urethral stricture formation post TURP may be closely related to electrical resistance and current leakage of appliances [24]. They investigated old and new monopolar and bipolar loops and found that the new unused bipolar loops had a low electrical resistance of 0.5–0.6 ohm, increasing with multiple use (for at least 60-min durations) to 1–115 ohm (mean 26.4 ohm), while none showed current leakage. In comparison, all monopolar loops exhibited current leakage after first use and showed relatively high resistance. These data indicate the superior durability of bipolar loops compared to their monopolar counterparts, and if reproduced in currently available bipolar loops, confirm their superior safety over their monopolar counterparts. But clearly, there is a need to develop bipolar continuous-flow resectoscopes smaller than 27F in diameter in the not-too-distant future.

Transitional cell tumor resection

Bipolar systems are being used to resect transitional cell tumors in the bladder (and possibly increasingly so in the renal pelvis in due course). Less char will mean better potential histologic analysis, but use of an isotonic solution means that loose cancer cells from higher-grade bladder tumors will not be lysed as they are in a bladder full of hypotonic irrigant such as sterile water, leaving greater theoretical possibility of seeding viable cancer cells (though this has not been substantiated experimentally to date). Another potential advantage is reduced stimulation of the obturator nerve, and thereby less risk of inadvertent bladder perforation. Futhermore, bipolar resection is a useful tool for resecting tumors in patients with a cardiac pacemaker. There have been recent suggested modifications in electrode design for bladder tumor resection, and these may be matched with availability of bipolar electrodes, including the possibilities that accompany the development of thick and thin electrodes.

Cost

This issue has not been studied in detail. A financial analysis by Ruiz-Deya *et al.* showed the cost of bipolar saline TURP to be 10.56% less than that of conventional monopolar TURP [25]. This translated into a cost saving of US$1138 per patient in their institution, but they did not take into account the cost of purchasing a new dedicated generator, a new resectoscope, or at least a new working element, active electrodes that are more than 8–10 times the cost of a regular loop, not to mention a longer possible operating room time (which could be offset by lower morbidity). Furthermore, there is as yet no good sense of loop durability in long resections, and cost will increase if more than one loop has to be used in larger glands. Thinner loops may also be damaged or deformed by repeated contact with prostatic concretions of the variety that are sometimes encountered at the junction between transition and peripheral zones.

On the other hand, costs may be lowered in future through multispecialty use of the generator (in dermatologic, ENT, orthopedic, and gynecologic procedures), as well as its use in laparoscopic surgery, and will certainly go a long way to improving both its attractiveness and affordability throughout the developed world.

Conclusions

Transurethral bipolar electrosurgical vaporization and resection systems undoubtedly have future potential for a variety of reasons outlined in this chapter, particularly at a time when urologists may be tackling larger prostates endoscopically, given the dominance of the monotherapy medical treatment paradigm of the last decade or so. In the face of stiff competition from higher powered lasers (both holmium and KTP), whether this potential is bright, making it an indispensable tool in the prostate kitchen of tomorrow, or just a passing fad like so many other technologies that have failed to endure, will depend on mass acceptance of the technique in the established urologic workplace and particularly in training centers that will nurture the urologic surgeon of tomorrow. In order to achieve this, the cost comparisons and outcomes in appropriately designed larger multicenter studies, where bipolar loop resection is pitted against the enduring gold standard of monopolar resection and new challengers from the laser arena, must be forthcoming to establish a high-quality solid evidence base that will ultimately drive registration and reimbursement, without which no new technology can endure.

Monopolar transurethral resection of the prostate

Transurethral resection of the prostate (TURP) has been the gold standard in surgical management of patients with benign prostatic hyperplasia (BPH). The procedure has withstood the test of time, while many new, self-proclaimed "superior" procedures have failed to last in an era of procedure frenzy. The place of conventional TURP using monopolar energy has recently come under heavy scrutiny with the emergence of bipolar systems. The underlying principles of both monopolar and bipolar electrosurgical systems are similar, but the manner in which the current returns to the generator is different. However, until the long-term safety profile of the latter approach becomes established, monopolar TURP will continue to be an important tool in the therapeutic armamentarium of urologists dealing with BPH patients.

History

Electrosurgery had its beginning in 1882 when d'Arsonval found that high-frequency alternating current when passed through the body caused heating without muscle and nerve stimulation [1]. Young (1909) improved the endoscopic application of electrosurgery by using a fenestrated tube in place of an inner cutting tubular knife for the cold punch operation for prostatectomy [2]. This innovation allowed water to be infused between the electrode and the sheath, thereby improving vision and cooling the instrument. Edwin Beer (1910) is credited with being the first to make use of electrosurgery endoscopically by placing an electrode through a Nitze cystoscope to remove tumors of the bladder neck [3]. Stevens and Bugbee performed the first electrosurgical endoscopic incision of the prostate in 1913 [4, 5].

The development of the spark gap generator was a landmark invention which came into existence with the pioneering efforts of Liebel and Bovie (1924) [6]. This generator was able to produce both cutting and coagulating waveforms, which greatly facilitated hemostasis while resecting the prostate. Shortly after this invention, Stern (1926) developed the early resectoscope using a cutting loop consisting of a small ring of tungsten wire of approximately 0.5 cm in diameter [7]. The loop was placed at right angles to the end of an insulated shaft and was connected such that the loop could be made to slide easily. The radiofrequency current was then delivered continuously under water to excise prostate tissue. However, securing hemostasis was still an important issue. Davis, by using the Bovie generator, not only overcame this problem, but also became the first to use it for excision of large amounts of prostate tissue. Joseph McCarthy (1932) subsequently developed the McCarthy resectoscope, which bears significant resemblance to the modern resectoscopes. The invention of rod–lens optical system by Harold H. Hopkins (1959) and the addition of fiberoptic light transmission by Karl Storz (1960) marked further breakthroughs in modern endoscopy [8]. Since then, several refinements in instruments and technique have been made by outstanding urologists, but the basic principles have remained the same.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Electrosurgical basis of transurethral resection of the prostate

The entire concept of TURP (monopolar or bipolar) is based on the basic principles of electrosurgery. Ablation of the prostate is achieved by employing alternating current with wavelengths in the radiofrequency range. The standard alternating current, with frequencies in the 60-Hz range, is unsafe for use in this setting as it subjects the patient to the risk of excessive neuromuscular stimulation, leading to tonic–clonic contractions with rhabdomyolysis and cardiac arrhythmias. The role of an electrosurgical generator is to increase the frequency of this current to over 200 kHz, because at all frequencies above 100 kHz current can pass through the body with minimal neuromuscular stimulation and no risk of electrocution.

While using a monopolar system for TURP, the active electrode (cutting loop) is placed in contact with the prostate tissue. Inside the resectoscope, the electrical connection from the generator to the cutting loop is carefully insulated. When activated, the generator produces a high-frequency voltage which drives a high-frequency current through the patient. The current passes from the small active electrode (cutting loop) at the tissue interface, through the patient to a proportionately larger indifferent electrode, and subsequently back to the generator (Figure 132.1). Thus, in a monopolar TURP, the patient is part of the system. Alterations in the frequency of oscillation and wave form alter the quality of coagulation and cutting.

The current flowing through the patient heats the tissue in contact with the loop, the heat generated being proportional to the current density (current flowing per unit area). The current density is high only in the tissue neighboring the current loop, leading to vaporization of the fluid in the cells near the loop, which can be moved through the tissue almost without any mechanical force.

Types of current waveforms

The basic function of an electrosurgical unit is to fulgurate or coagulate tissue by use of low-frequency current and the incision of tissue with high-frequency current. Depending on the characteristics of the generator, a variety of current waveforms can be produced. The individual settings are governed by the machine and requirements of the surgical procedure. The historical terms coagulation and cutting waveform can be misleading as low-power settings in the cut mode produce excellent contact coagulation, while high-power settings in the coagulation mode will produce a cutting action.

Cutting waveform

Cutting current uses a pure, nonmodulated sinusoidal waveform (Figure 132.2). Electrosurgical cutting requires the generation of small arcs from the electrode to the tissue, which occur twice during each cycle at the maximum and minimum voltage of the sine wave. This implies that the frequency of these arcs will be double the frequency of the sine waves produced by the generator,

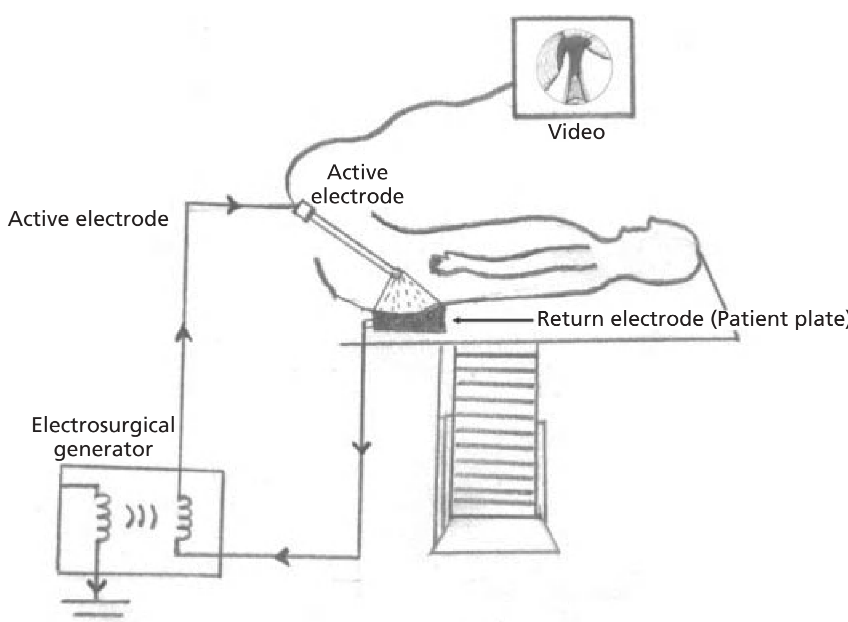

Figure 132.1 Monopolar circuit.

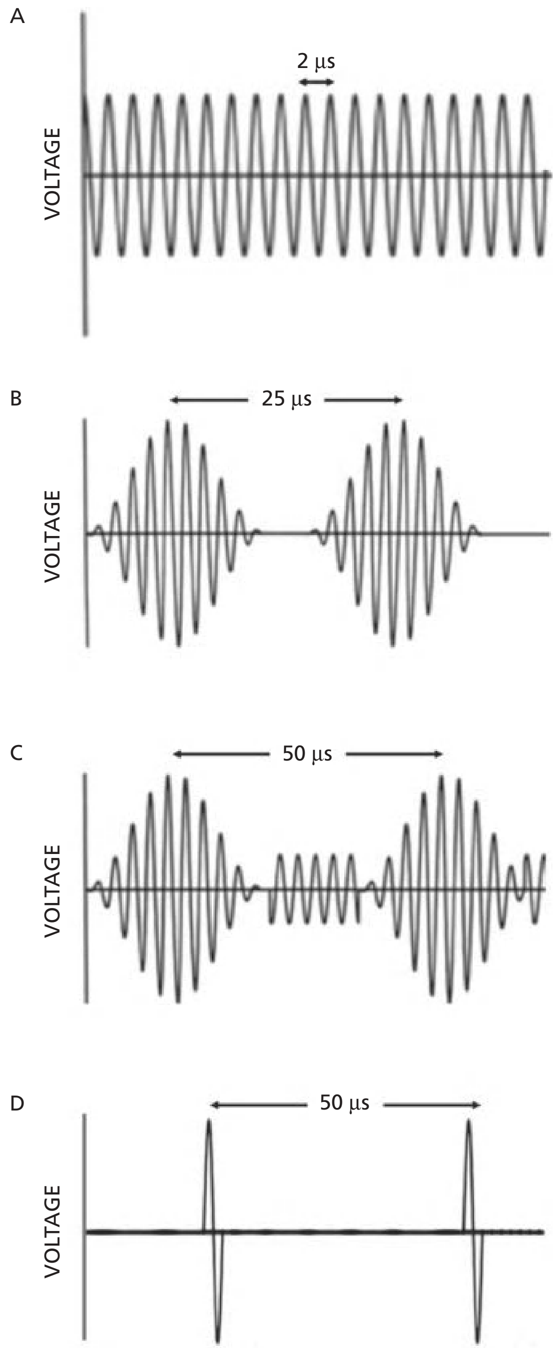

Figure 132.2 Waveforms. (A) Cutting current; (B) coagulating current; (C) blended current; (D) spray coagulation.

thereby facilitating a smooth cutting action without extensive thermal damage. This waveform achieves a higher average power when compared with any other alternating waveform of equal peak voltage (>500 V), allowing the voltage to be limited when compared with coagulation current. It is important to remember that the described cutting effect depends only on the magnitude of the current density, not on the frequency of the current. In general, cutting is produced by high tissue temperatures (>100° C), whereas coagulation is produced by tissue heating between 70° C and 100° C.

While performing TURP, a higher setting for the cutting current increases greatly the efficiency of the cut, while adding little to the danger of the procedure. On the other hand, too much cutting current produces a noticeable blue flame between the electrode and the tissue, which should be avoided. In general, small fibrous glands or bladder neck contractures are best treated by using a small-caliber loop with a high-intensity cutting current.

Coagulation waveform

Coagulation current is a highly dampened current characterized by extensive wave modulation in which the generator supplies current for less than 50% of the activation time. This produces intermittent bursts of damped sine waves of high peak voltages, up to 10 000 V (Figure 132.2). When employed, with the active electrode in contact with the tissue, these peak voltages result in high tissue temperatures, and hence significant thermal destruction, making this type of current particularly suited for the coagulation of bleeding vessels. Therefore, when this type of current is used in TURP, the intensity should be as low as will reasonably coagulate the tissue, and the time of application should be as short as possible.

Blended waveform

Blended currents are actually a combination of the above two waveforms, created by modulating a second, lower frequency, higher amplitude sine wave with the sine wave from the cutting generator, producing a higher peak-to-peak voltage. This waveform typically supplies current for only 50–80% of the activation period. The new waveform is then delivered in intermittent bursts at a rate determined by the settings of the electrosurgical generator (Figure 132.2). Blended currents allow the surgeon to cleanly divide tissue while maintaining a variable degree of hemostasis, depending on the amount of coagulating current used. Because more vascular glands have higher moisture content, this type of tissue is best resected using a blended current to maximize cutting and coagulation properties.

Spray coagulation waveform

This waveform is highly intermittent, with the generator supplying current for only 5% of the activation time (Figure 132.2). It is also high voltage (up to 10 kV) to produce long sparks between electrode and tissue. Operating in this mode, the active electrode does not

touch the tissue, but instead, the high voltage causes air ionization and sparking. This mode uses relatively low current output (approximately 0.1 A) and thus leads to a thin layer of tissue necrosis with little depth of thermal damage.

Irrigation fluids

A hypo-osmolar irrigation fluid (1.5% glycine) is used that is nonconducting and not too rapidly absorbed. Despite having an osmolality of 200 mOsm/kg, it has played a role in reducing the risk of hemolysis and death by more than 50% from the days when distilled water was used for irrigation [9]. A variety of other electrically nonconducting irrigation fluids like 5% dextrose, 3% mannitol, and 3% sorbitol have also been used. Normal saline is not suitable for monopolar TURP as it may prevent the creation of a cutting arc because of its conductivity.

Indications for transurethral resection of the prostate

In 1989, the American Urological Association (AUA) initiated the Guideline Panel for Diagnosis and Management of BPH, which was later taken over by the Agency for Health Care Policy and Research (AHCPR) [10]. The panel subsequently recommended the AUA-7 Symptom Index for formal assessment of a patient's symptoms. The current indications for performing TURP are listed in Table 132.1.

Preoperative evaluation

Patient assessment

As most patients undergoing TURP are elderly, assessment of the renal, cardiac, pulmonary, and general physiologic status is of paramount importance because major derangements in these vital organs are important predictors of postoperative outcome. In addition to routine blood investigations, including hemoglobin, complete and differential blood counts, blood sugar, prothrombin time, and partial thromboplastin time, renal function tests (including serum creatinine and blood urea nitrogen) should be obtained from all the patients. Surgery should be postponed and catheter drainage done in patients with impaired renal function due to obstructive uropathy. Such an approach allows maximum possible improvement in renal function before the patient is taken up for surgery. An ultrasound abdomen with special emphasis on the kidney, ureter, and bladder (KUB) region should be obtained to assess the prostate size and postvoid residual volume (PVR). In patients who have not been catheterized, uroflowmetry is considered the single best noninvasive test to detect lower urinary tract obstruction. Pressure flow studies should only be done when the diagnosis is unclear. A prior cystoscopic assessment is generally not necessary and it can be done at the time of the procedure.

Table 132.1 Current indications for transurethral resection of the prostate.

Moderate (8–19)-to-severe (20–35) lower urinary tract symptoms (LUTS) not responding to medical treatment
Refractory urinary retention with at least one failed attempt at catheter removal
Chronic retention with back pressure changes, leading to:
• Hydronephrosis
• Renal insufficiency
Complications of benign prostatic hyperplasia (BPH), including:
• Recurrent urinary tract infection
• Recurrent gross hematuria
• Bladder diverticula
• Bladder stones

Perioperative antibiotics

Patients with evidence of infection should be treated prior to the planned procedure. Although the impact of prophylactic antibiotics in reducing postoperative infection was refuted by some authors, most of the available literature supports their beneficial role [11–16]. The antibiotic should cover both Gram-positive and Gram-negative organisms. Patients with an indwelling catheter are at a higher risk, even if no preoperative evidence of infection is detected. It is our practice to routinely administer a single intravenous dose of a broad-spectrum prophylactic antimicrobial 1 h before the procedure. The patient is subsequently continued on oral antibiotics until they are catheter free.

Anesthesia

The choice of anesthetic should be individualized, and the procedure can be performed under spinal epidural or general anesthesia with similar results [17–19]. Small volume glands (<40 g) can also be resected under local anesthesia, especially when associated major comorbidities are present [20, 21].

Surgical technique

The patient is placed in the modified lithotomy position. Care is taken to avoid overextension at the hip joint, and adequate padding is used for bony prominences.

Cystourethroscopy, if not done beforehand, is done as the first step to assess the distal urethra, position of verumontanum, size and configuration of the prostate,

bladder neck, urinary bladder, and both ureteric orifices. In case of urethral narrowing, urethral dilators are used to dilate it to 28F. Sometimes, internal urethrotomy may be required to accomplish this. Meatal dilatation or dorsal meatotomy (using a curved blade or Otis urethrotome) is done if the meatus is narrow.

The resection technique may vary according to the size or configuration of the prostate, but should be based on an orderly plan. There are several different surgical techniques described for TURP adenoma; however, the principle remains the same, i.e. step-by-step resection and coagulation of each quadrant of prostatic lobes (Figures 132.3 and 132.4). Each operator is expected to familiarize themselves with any one approach which they are comfortable with, and then to master it with experience. A commonly used approach,

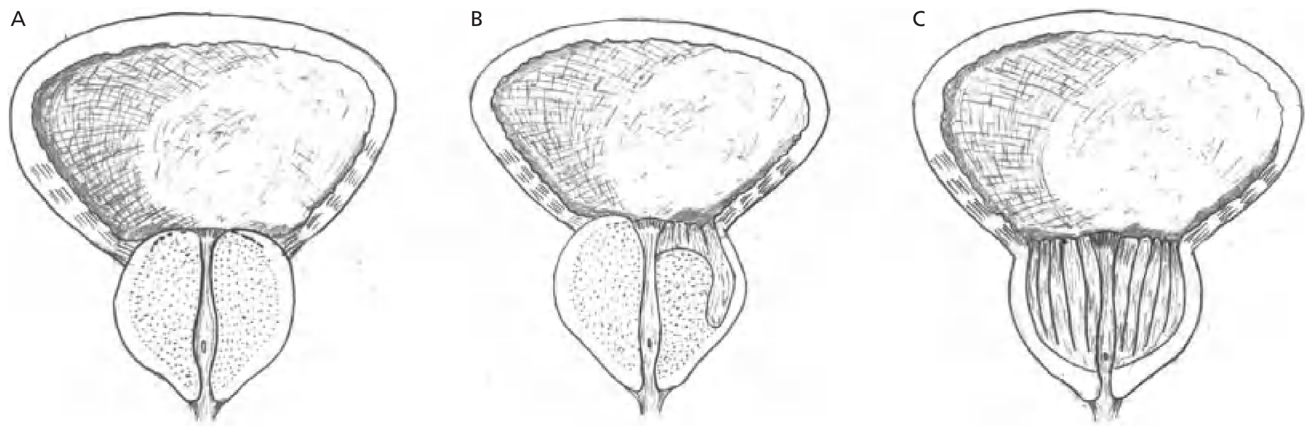

Figure 132.3 (A–C) Stages of transurethral resection of the prostate: coronal representation.

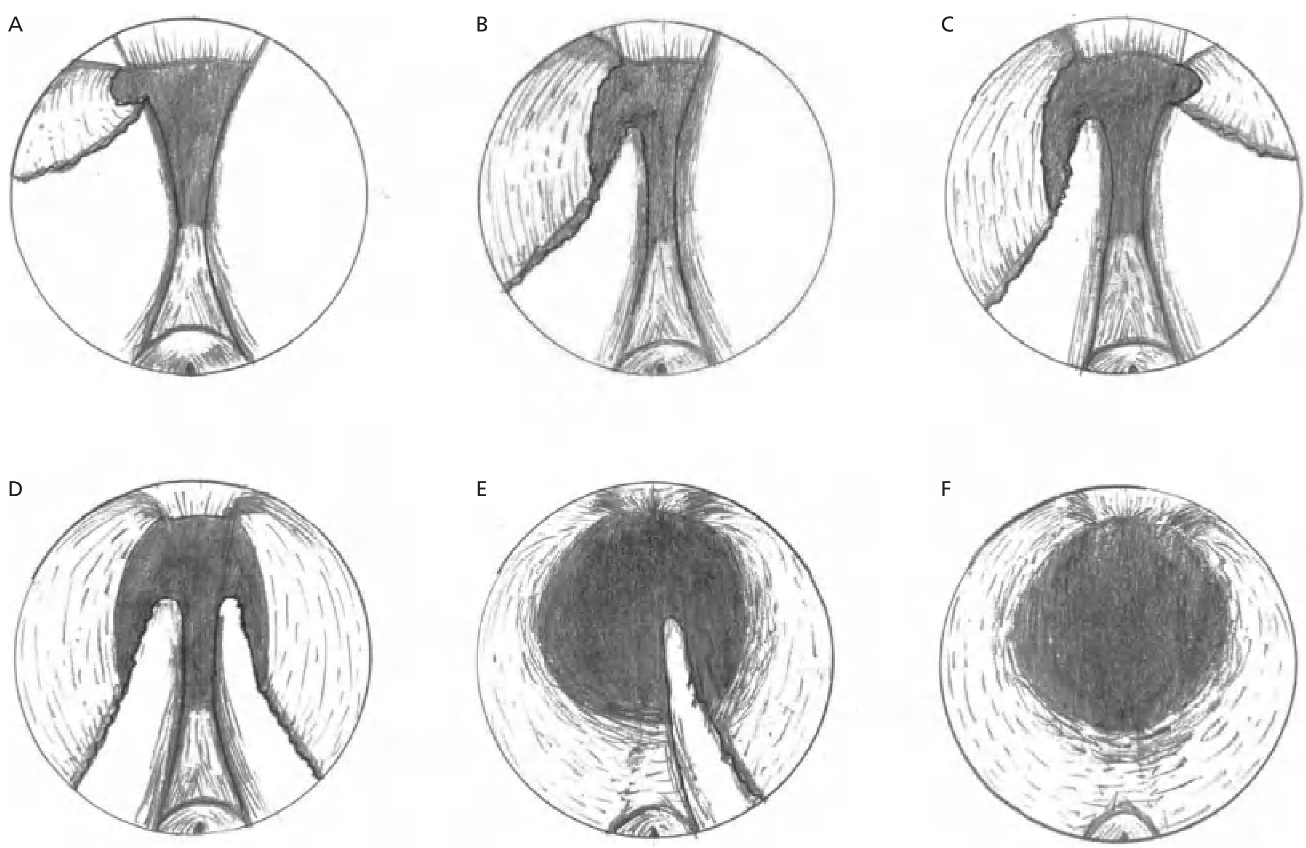

Figure 132.4 (A–F) Stages of transurethral resection of the prostate: Endoscopic view.

popularized by Nesbit, utilizes the principle of resecting anteriorly first so that the adenomatous tissue drops down, allowing the surgeon to resect from the top downwards rather than from the floor upwards.

A 24 or 26F size resctoscope, the continuous irrigation variety (Iglesias), is the most commonly employed equipment these days. The resectoscope is placed at the level of the verumontanum and the adenoma is resected in quadrants. Resection begins at 12 o'clock at the bladder neck, and is then carried down anticlockwise to the 9 o'clock position in a stepwise fashion to a depth where circular fibers of the bladder neck become visible. The resection is carried down to the surgical capsule, which is recognized as a rather fibrous structure compared with the granular appearance of the prostatic adenoma. The other anterior quadrant, from 12 to 3 'o'clock, is next resected clockwise.

Resection of the anterior quadrants results in the lateral lobes falling towards the floor. Resection of right lateral lobe is started at approximately the 9 o'clock position and continued in an anticlockwise fashion. The posterior portion on the floor of the prostatic fossa is resected. The resection is carried to the right side of the verumontanum. For the left lobe, a similar procedure is started at approximately 3 o'clock and carried clockwise to the left side of the verumontanum. As the lower two quadrants in the floor of the prostate are resected, the capsule fibers become less distinct. After completion of the lateral lobes, the tissue at 6 o'clock, including the median lobe if present, can then be resected up to the verumontanum. Care must be taken not to resect too deeply in the region of the posterior aspect of the vesical neck to prevent undermining of the trigone.

Large adenomas can be resected using "'encirclement," a modification of the above-mentioned technique. During resection of the lateral lobes, a groove is created between the bulk of adenoma tissue and the surgical capsule by working the resectoscope loop along the capsule, allowing the lobe to fall to the floor. The loop works somewhat like the finger of the operating surgeon in the open transvesical prostatectomy, separating the lobe from the surgical capsule of prostate. The procedure is done first on one side and then on the other side. Finally, the remaining bulk of tissue on the floor, which by now is mostly devascularized, can be resected quickly to complete the procedure.

Another variation of the technique, popularized by Blandy, starts with resection of the floor at the 6 o'clock position, including the median lobe if present. This is followed by resection of each lateral lobe from the 12 'o'clock down to the 6 'o'clock position in the standard fashion. The advantage of this approach is to establish the tissue planes and landmarks at the beginning of the operation. This approach can be especially useful in prostates with a large median lobe.

Towards the end, the apical portion of the lobe remains, which is resected last. Care must be taken to avoid extending the resection beyond the level of veru to protect the external sphincter mechanism, which lies just distal to it. The most common area of damage to the external sphincter is at the 12 o'clock position. Thus, care must be taken as the 12 o'clock position is approached. The resection, especially the apical portion, may be performed with a finger in the rectum, for which a rectal shield can be put in place at the beginning of the operation.

When the resection is completed, the resectoscope is pulled just distal to the verumontanum, to see that there is no falling or obstructing tissue. Any remaining adenoma tissue can be judiciously trimmed down to the surgical capsule, taking care not to damage the sphincter mechanism.

Hemostasis is of prime importance, and must be maintained meticulously throughout the operation. The arterial bleeders are best coagulated at the level of the surgical capsule using spray coagulation. Complete hemostasis must be achieved at each stage, before resection proceeds to the other quadrant.

"Hemi-resection" of the prostate

TURP for large glands may be associated with significant morbidity, mainly due to absorption of irrigant and blood loss. When extensive resection of the prostate tissue is carried out, opening of venous sinuses can be associated with troublesome bleeding and/or excessive absorption of fluid, resulting in "TUR syndrome."

Similarly, in medically compromised elderly individuals (cardiomyopathy, ischemic heart disease, chronic obstructive respiratory disease, renal insufficiency, etc.) standard TURP may carry greater risk. In such patients the procedure may sometimes require to be terminated prematurely due to blood loss and/or excessive fluid absorption, because of the prolonged operating time.

However, incomplete resection leads to a large raw surface. Good hemostasis is not achieved because of the retraction of the blood vessels within the adenoma, leading to a greater incidence of hemorrhage and infection. In addition, incomplete resection of the prostate leads to poor flow rates postoperatively, and recurrent retention due to the "falling in" of the residual adenoma. It is also associated with a higher complication rate of reactionary and secondary hemorrhage, persistent postoperative urinary infection, and early recurrence [22].

In such a situation, an alternative solution is termination of the procedure after "complete" resection of one lateral lobe (and the median lobe, if present) of the prostate. This procedure, termed "hemi-resection" of the prostate (Figure 132.5), allows completion of the procedure quickly to avoid complications of excessive blood

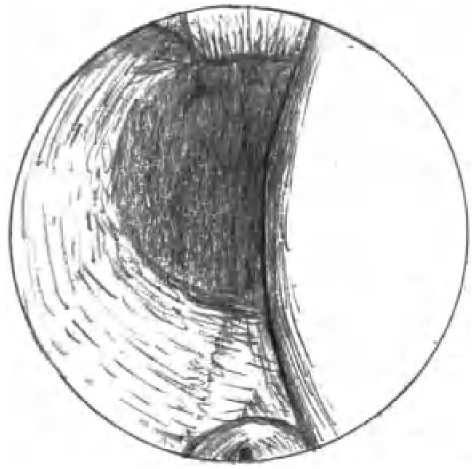

Figure 132.5 "Hemi-resection": endoscopic view.

loss and/or fluid absorption, while at the same time avoids the problems associated with "incomplete" resection.

The patients undergoing hemi-resection have the advantage of shorter operating time and less blood loss compared to those undergoing standard TURP. At the same time, complete resection of one lateral lobe (and the median lobe if present) prevents the complications of hemorrhage and persistent infection associated with incomplete resection, and ensures a good channel for adequate flow. The other lateral lobe that is left untouched remains attached to the surgical capsule of prostate and therefore does not "fall in" to obstruct the channel and increase the incidence of postoperative retention of urine. In addition, there is no raw area of incomplete resection as the mucosa over the unresected lobe remains intact.

In a propective randomized trial at our center in a series of 163 patients, the results of standard TURP and prostatic hemi-resection were found to be comparable in terms of reduction of PVR, improvement in symptom score, and peak flow rate [23]. No patient developed retention of urine in the postoperative period. The incidence of blood loss and TUR syndrome were lower in the hemi-resection group.

Prostatic "'hemi-resection" allows early termination of TURP in case of need, to avoid complications of excessive blood loss and fluid absorption. At the same time, it avoids the problems associated with "incomplete" resection. "'Hemi-resection" or "hemi-TUR" may be considered an acceptable option if the surgeon gets into trouble in the middle of an operation, or even as an elective operation in men with large glands and severe medical comorbidity, without compromising the basic principles of TUR surgery.

Postoperative care

Most urologists prefer to apply traction on the irrigation catheter for a period of 2–6 h. Continuous irrigation is provided with prewarmed fluids, with care taken to ensure proper outflow. The early postoperative period requires careful monitoring for prompt recognition of any complications. It is desirable to have an assessment of hemoglobin and electrolytes in this period. Patients are made to ambulate after traction is removed. Antimicrobials are continued until the patient is catheter free (i.e. 3–5 days).

Outcomes

The AHCPR panel (McConnell *et al*.) conducted a meta-analysis of various clinical studies and found the results of TURP to be significantly better in comparison to other less invasive procedures [24]. TURP improved symptoms in 70–96% of patients (mean 85%).

The mortality rates following TURP have shown a significant decline since the introduction of the procedure. The current mortality rates range from 0% to 0.25% [25]. This reduction indicates that progress has been made in making the procedure safer than it originally was. Technologic advances, such as microprocessor-controlled units, better armamentarium such as video TURP, and better training have contributed to this improvement.

Complications

Early complications

Hemorrhage

Hemorrhage is the most frequent complication. Larger glands and resection times of longer than 90 min are associated with a higher incidence of bleeding. The bleed can be arterial or venous and complicates both intraoperative and postoperative management. Arterial bleeding should be suspected if the irrigation catheter shows continuous passage of bright red blood. As a general principle, during resection all bleeding from an area of the prostatic fossa should be controlled using coagulation before moving to another area. Venous bleeding is darker and generally occurs after a period of initial clear irrigant in the postoperative period. Reapplication of traction on the catheter with or without over-inflation of the balloon can be useful in these cases. Excessive bleeding, especially if suspected to be arterial, may require repeat cystoscopy with electrosurgical coagulation to control the bleeding.

Resection errors

Over-resection with perforation of the prostatic capsule leads to extravasation of irrigant. It is characterized by restlessness, vomiting, and abdominal pain localized to the lower abdomen and back (a noticeable feature in a patient who has undergone spinal anesthesia). Immediate termination of the procedure with control of bleeding is of paramount importance in these patients. Most patients respond well to a period of catheter drainage and antibiotics.

TUR syndrome

This complex syndrome of fluid overload, dilutional hyponatremia, and hemolysis occurs due to systemic absorption of large amounts of irrigant, especially in patients with a gland size larger than 45 g and a resection time of more than 90 min. Mebust *et al*. observed that TUR syndrome occurred in 2% of patients [10]. The syndrome may occur as quickly as 15 min after the resection starts or up to 24 h postoperatively [26–29]. It is characterized by confusion, nausea, vomiting, hypertension, bradycardia, and visual disturbances. Monitoring the serum sodium concentration is important as the syndrome does not occur until the serum sodium falls below 125 mEq/dL. Intravenous hypertonic saline, diuretics, and termination of the procedure may be required when this happens. Madsen and Naber observed that limiting the height of the irrigation bottle to 60 cm above the prostate reduced the intravascular fluid absorption [30]. Leaving a rim of tissue on the capsule until the end of the procedure, where it can be left if signs of TUR syndrome are evident, may reduce the risk of absorption due to opening of prostatic sinuses [31, 32].

Obturator nerve stimulation

Most instances of obturator nerve stimulation occur following transurethral resection of bladder tumors and TURP is very infrequently implicated. When it occurs, stimulation of the obturator nerve produces a sudden thigh movement that can cause the cutting loop to bite more deeply and often at undesired locations. Various modalities have been tried to prevent adductor spasm during spinal anesthesia, ranging from local blockade of the obturator nerve, periprostatic and subvesical lignocaine infiltration, changing the site of the inactive electrode, reduction of the electrocoagulation voltage, and general anesthesia with muscle relaxants. However, local blockade of the obturator nerve seems to be the most effective in preventing this complication [33–35].

Intraoperative priapism

Intraoperative penile erection may be managed by injecting small boluses of an alpha-adrenergic agent (dilute ephedrine or phenylephrine) into the corpora cavernosa.

Sepsis

Pre-existing urinary tract infection should always be rectified and managed before undertaking TURP. Patients with long-standing indwelling catheters are at greater risk. Once infection is recognized, broad-spectrum empirical antibiotic therapy is started. Perioperative antibiotic prophylaxis has been shown to reduce the risk of events related to postoperative infection.

Late complications

Bladder neck contracture

This complication occurs 4–6 weeks after surgery and should be suspected in a patient complaining of poor stream who initially had a good flow postoperatively. Zwergel *et al*. reported bladder neck contracture in up to 2.7% patients following TURP [36]. It can be treated by bladder neck incision with a Collings knife.

Urethral stricture

Urethral strictures following TURP have been reported in 1.7% patients and can occur at the fossa navicularis (most commonly), bulbar urethra or prostato–membranous junction [36]. Strictures can be treated with sequential urethral dilatation and optical internal urethrotomy. The incidence of post-TURP stricture has declined significantly owing to the availability of better electrosurgical equipment and smaller sized resectoscopes, limiting the resection time, and use of lubricant jelly.

Incontinence

Thermal injury to the sphincter is the underlying mechanism in most patients who develop this complication of TURP. Detrusor instability and residual adenoma blocking the external sphincter mechanism may also contribute to this complaint. Transient incontinence is relatively common following the procedure, and most patients show spontaneous improvement in a few weeks or months. Kegel exercises and anticholinergics are useful in these patients. For refractory cases, collagen injections and artificial sphincters are needed.

Impotence

A small number of patients report impotence following the procedure, which may be psychogenic or due to age and prolonged abstinence following the operation. This complication needs to be studied well to eliminate the discrepancy in the reported literature (incidence 4–40%). In fully potent men, the risk of impotence after transurethral prostatectomy is fairly low, but it is higher in men who already have a degree of erectile failure. This risk has also been reported to be related to the incidence of capsular perforation at the time of surgery [37].

Tscholl *et al*. used the Snap Gauge tests to assess the incidence of erectile impotence in patients with intact potency preoperatively. Of the 98 patients studied, they observed that erectile dysfunction persisted in eight (8.3%) patients 3 months after the procedure [38]. Importantly, in their study 26 patients who had potency-related problems postoperatively improved in the subsequent 3 months.

Comparison with bipolar transurethral resection of the prostate

Monopolar TURP does suffer from a few inherent limitations. First, the patient is a part of the electrosurgical circuit, which can cause deep heating and the possibility of nerve damage. Second, the use of a hypo-osmolar irrigant implies that electrolyte imbalance and TUR syndrome will always remain bothersome concerns.

In recent years, bipolar TURP has emerged as an alternative to the standard monopolar TURP. Advocates of bipolar TURP cite comparable clinical efficacy with a better safety profile, especially in terms of lower instances of TUR syndrome and better hemostatic capability, as the primary reason for its superiority. Besides, some studies also indicate that duration of catheterization and hospital stay are shorter with this approach. These data seem promising, but large randomized trials with long-term follow-up are needed to further clarify issues related to long-term complications and cost, before bipolar TURP becomes universally accepted for managing BPH.

CHAPTER 133
Bipolar Resection

Jaspreet S. Sandhu
Department of Surgery/Urology, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Introduction

Bipolar transurethral resection of the prostate (BiTURP) is an endoscopic technique used in the surgical management of lower urinary tract symptoms (LUTS) secondary to benign prostatic hyperplasia (BPH). It is a design modification of the monopolar transurethral resection of the prostate (TURP), utilizing a specialized resectoscope and loop that incorporates the active electrode on the loop and return electrode on a separate insulated part of the loop or on the inner sheath of the resectoscope. This allows the procedure to be performed using normal saline as an irrigant, thereby limiting the risk of dilutional hyponatremia (or transurethral resection syndrome), and with potentially less stray current because of the very short distance between the active and return electrodes. The electrode can be used to resect as well as to coagulate. Modifications of the electrode also allow vaporization, which will be discussed in a subsequent section.

Monopolar TURP, as described in Chapter 132, is a transurethral endoscopic procedure that relies on electrosurgical resection of prostate adenoma, followed by removal of "prostate chips" from the bladder with an aqueous evacuator. It has been performed since early in the last century, has evolved to be the procedure of choice for surgical treatment of LUTS secondary to BPH, and is often called the "gold standard" surgical treatment for BPH/LUTS. While monopolar TURP is known to be efficacious for the treatment of LUTS secondary to BPH, it is associated with reasonably high rates of complications, including hematuria, reoperation, dilutional hyponatremia, and the need for blood transfusion [1]. Advances in optics and energy generation/delivery systems have decreased complications significantly in modern times [2]. However, the number of TURPs performed in the USA continues to decrease yearly, perhaps because of the perception of increased morbidity [3].

The rationale for bipolar TURP (BiTURP), therefore, is straightforward: to limit the risk of dilutional hyponatremia while leveraging transurethral resection skills that most urologist acquire during training and practice. Most authorities suggest limiting monopolar TURP times to 60 min, because of the increasing risk of dilutional hyponatremia with increasing resection time under glycine irrigation [4]. The fact that BiTURP uses normal saline as an irrigant effectively eliminates this risk and allows operators to use this technique for as long as needed. This is particularly advantageous in patients with large volume prostates or in medical education.

It should be noted that this technique is actually an evolution of transurethral vaporization of the prostate [5], a monopolar technique that uses higher current and electrodes with broader contact with tissue to "vaporize" tissue at the cut edge of the resection. BiTURP has been referred to as bipolar vaporization of the prostate, plasmakinetic vaporization of the prostate or bipolar resection of the prostate. This nomenclature adds to confusion, particularly with strictly ablative techniques such as KTP laser vaporization of the prostate or bipolar button vaporization electrode. The "vaporization" referred to in BiTURP is actually the vaporization that occurs of tissue in contact with the cutting loop (active

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

electrode). This is similar to what happens to tissue in contact with the cutting electrode during monopolar TURP. BiTURP relies on the creation of a "plasma corona" at the electrode and this results in roughly 20% of the tissue being vaporized, with the rest resected as prostate chips [6].

BiTURP was first introduced in humans in the early part of this century [7]. The initial reports touted this technique's ability to use bipolar current through an isotonic irrigant media with results similar to TURP. Most subsequent reports have focused on technologies from different manufacturers and primarily compared results to TURP in either randomized controlled trials or comparative trials.

Patient selection

Surgical therapy is the mainstay for treatment of LUTS secondary to BPH and refractory to medical therapy. Current practice is to offer minimally invasive surgery to patients who do not want or are unfit for a more involved operation . Endoscopic surgery is the gold standard for treatment of LUTS secondary to BPH, with open surgery reserved for those patients with large glands or those who need concomitant procedures [8].

The most recent American Urological Association (AUA) guidelines [8] on the management of BPH/LUTS recommend TURP as the surgical treatment of choice for men with moderate-to-severe LUTS who are bothered by their symptoms. Because these guidelines were published near the advent of BiTURP, they state that saline bipolar technologies be considered experimental. The revised version of the AUA guidelines is expected shortly and will likely recommend BiTURP as an option for surgical treatment of moderate-to-severe BPH/LUTS.

Surgical equipment

BiTURP is an endoscopic resection technique that uses a continuous flow resectoscope and a specially designed loop and inner sheath that varies by manufacturer and use. As opposed to monopolar TURP, the irrigant media is usually 0.9% normal saline. Generators are also matched to the loop used and adjust voltage based on impedance to keep current constant.

Technology

Bipolar technology platforms currently available are the PK system by Gyrus/ACMI, an Olympus Corporation (Tokyo, Japan) company, the TURis system by Olympus Corporation, and a bipolar resection system by Karl Storz (Tuttlingen, Germany). Each of these systems uses a continuous flow resectoscope and relies on an active electrode on the cutting element of the loop, with the ability to generate a plasma corona vaporization field in normal saline. The difference between these platforms is the location of the return electrode. Because BiTURP relies on the ability to generate a current between two poles and the closer the two poles, the lower the voltage needed to generate a current, the return pole (electrode) has to be in close proximity to the active electrode. As such, the return electrode of the PK system is on the loop itself, separated from the cutting element by a few millimeters of insulation (Figure 133.1). The return electrode TURis system is on the inner sheath of the resectosope (Figure 133.2), and the return electrode for the Storz system is on the loop opposite the cutting element.

BiTURP, which typically needs a lower voltage differential to generate a high current because of the short distance needed to close the circuit, relies on generators that can change voltage based on tissue impedance and therefore keep current constant. Specially designed generators are matched to each platform. All generators have preset default settings; typical settings for "cutting" are high power (200–280 W for TURis, 160–200 W for PK) and settings for "coagulation" are lower power (120 W for TURis and 80 W for PK). Different loops are also available for the PK system and the TURis system to allow resection of bladder tumors or to perform vaporization without resection. All currently available loop electrodes are single use. Figure 133.3 is an illustration of the Gyrus PK generator.

Surgical technique

The surgical technique for BiTURP is similar to monopolar TURP, with a few unique aspects. As in other transurethral procedures, preoperative antibiotics should be given. Regional anesthesia (e.g. spinal) or general anesthesia may be used. It is important to note that there should be no dilutional hyponatremia with BiTURP, eliminating the need to monitor mental status and allowing general anesthesia to be used at the anesthesiologist's discretion.

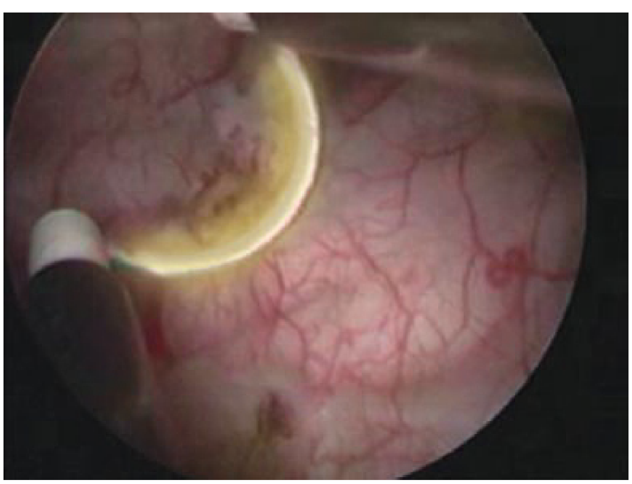

Figure 133.4 Plasma corona firing in the bladder.

Initial intubation of the urethra should be performed with the help of a visual obturator. If needed a urethrotomy may be performed to allow entry of larger resectoscopes. Once the bladder is reasonably filled, continuous irrigation should be started, typically with the outflow port open to gravity drainage. Resection begins with resection of the intravesical component and the median lobe of the prostate. Unlike the monopolar TURP, the cutting electrode loop needs to develop a "plasma corona" prior to the start of resection (Figure 133.4). The loop should not be in contact with prostate tissue when the operator initiates the cutting current via the foot pedal. At the beginning of the case, this is typically done with the electrode in the bladder and slightly off the prostate surface. Once the corona is formed, resection proceeds in an antegrade fashion for the length of the loop excursion. Prostate chips are formed similar to those in monopolar TURP and are forced into the bladder by the inflow of normal saline irrigant.

The resection should be performed systematically as in a conventional TURP with prostate landmarks used to limit resection, in particular the verumontanum at the apex. Typically, the intravesical component is first resected, followed by the median lobe from the bladder neck to the verumontanum. Care should be taken to avoid injury to the ureteral orifices during this step. Next, one of the two lateral lobes is resected in its entirety prior to proceeding to the other one. Finally, apical tissue and anterior tissue are resected. During resection, the plasma should always be visible. This is especially important as the procedure proceeds, because charred tissue accumulating on the surface of the cutting loop, will add impedance to the circuit. As stated above, the corona should be initiated within the bladder or in the lumen of the prostatic urethra without contacting prostate tissue. If the time between stepping on the

cutting pedal and the formation of the plasma corona starts to become long, the operator should place the loop in the center of the bladder and allow the plasma to fire for a few seconds. This will clean the loop electrode and allow more efficient vaporization.

Once the surgical endpoint is reached, specifically the entire adenoma has been resected from bladder neck to verumontanum and capsular fibers are visible, hemostasis should be achieved. This is done with the coagulation current. During coagulation, no plasma is formed. Instead of point coagulation, as in monopolar TURP, BiTURP relies on coagulating a surface around the bleeding vessel. This is likely due to the shallow penetration of current during BiTURP. Of note, coagulation should be performed intermittently throughout the procedure if significant bleeding is encountered as this will improve visibility during the case.

Prostate chips, which should have been deposited in the bladder, are removed with help of an aqueous evacuator. Once all chips have been removed and this has been confirmed by a final survey of the base of the bladder and prostate fossa, a three-way urethral catheter is inserted and continuous bladder irrigation is begun. Typically, this irrigation is titrated off by the first postoperative day, and the catheter removed. Patients are discharged with a few days of antibiotics. The prostate chips are evaluated by surgical pathologists in a manner similar to that for prostate chips removed during a monopolar TURP, and the same conventions are used to report findings, including T1a or T1b prostate cancer in cases of previously unsuspected prostate cancer. If T1a or T1b prostate cancer is found and the patient is a candidate for prostate cancer treatment, a transrectal ultrasound (TRUS)-guided biopsy of the prostate should be performed once the patient has healed from the BiTURP, typically 6 weeks to 3 months after the procedure.

Post-discharge management is similar to that with monopolar TURP and is dependent on the surgeon. Typically, patients can expect mild hematuria which resolves within days and can also expect a temporary increase in frequency and urgency of urination. There may be a period of recurrent hematuria 2–4 weeks after the procedure, managed by increasing oral hydration. Follow-up visits are usually at the 3-, 6-, and 12-month time points. At each follow-up visit, the International Prostate Symptom Score (IPSS) is collected along with uroflowmetry data and measurement of postvoid residual urine (PVR). A serum prostate-specific antigen (PSA) should be obtained at the 12-month visit if indicated. Of note, if patients were candidates for prostate cancer screening at the time of BiTURP, a preoperative serum PSA and digital rectal examination should have been performed, and if either one was abnormal, a TRUS-guided biopsy of the prostate should also have been performed.

Efficacy

The first reports of BiTURP in humans came in the early part of this century. Botto *et al*. published a pilot study in 2001 of 42 patients who underwent electrovaporization of the prostate using saline bipolar electrocautery with the Gyrus system [7]. These investigators reported 3-month results following treatment of men with symptomatic BPH without suspected prostate cancer. They noted that no men had significant postoperative bleeding and the mean catheterization time was 1.4 days. Two of the 42 patients developed urethral strictures requiring treatment. Mean length of stay was 2.2 days. At 3 months, IPSS decreased from 16 at baseline to 9 and peak flow rate (Qmax) on uroflowmetry increased from 7.9 mL/s to 19.7 mL/s. Based on these short-term results, the authors concluded that the Gyrus system for electrovaporization of the prostate is useful and safe.

Yang *et al*. subsequently performed a randomized prospective study comparing the Gyrus BiTURP to conventional monopolar TURP [9]. They enrolled 117 patients, 58 in the BiTURP group and 59 in the monopolar TURP group, and followed these patients for 3 months. The authors noted that both groups reported significant improvements in IPSS (BiTURP, 20.9 preoperatively to 10.8 at 3 months; TURP, 21.6 preoperatively to 11.1 at 3 months) and Qmax (BiTURP, 10.4 mL/s to 17.1 mL/s; TURP, 10.9 mL/s to 14.8 mL/s), but no statistically significant difference between groups. In their study, complications occurred at the same rate in both groups; notably only one patient developed TUR syndrome in the monopolar TURP group and none in the BiTURP group. These authors concluded that monopolar TURP and BiTURP yielded similar results but longer follow-up was necessary to establish long-term efficacy.

At roughly the same time, Fagerstrom *et al*. performed a randomized trial comparing operative performance of the Olympus TURis BiTURP to conventional monopolar TURP [10]. These investigators randomized 202 patients, 185 of whom were evaluable. They noted that both groups had similar tissue resection weight, but that blood loss and hemoglobin decrease were more in the TURP group than the BiTURP group. These authors concluded that BiTURP causes less bleeding that the monopolar TURP technique.

Starkman and Santucci retrospectively compared their results for 18 consecutive patients who underwent monopolar TURP with a subsequent consecutive group of 25 patients who underwent Gyrus PK BiTURP [11]. These authors reported results after an observation period of approximately 1.5 years to evaluate long-term complications. Weights of resected tissue were similar in both groups and they noted shorter catheterization times (3.2 days for monopolar TURP vs 1.8 days for BiTURP) and shorter length of stay with BiTURP (2.1

days for monopolar TURP vs 1.2 days for BiTURP). Acute complications included two of 18 monopolar TURP patients with dilutional hyponatremia and interestingly, one of 25 BiTURP patients with dilutional hyponatremia. Other acute complications were minor, but higher in the monopolar TURP group as compared to the BiTURP group (33% vs 16%). Long-term complications consisted of one bulbar urethral stricture in each group, a patient who developed a bladder neck contracture related to radiotherapy for a subsequent prostate cancer diagnosis in the BiTURP group, and a patient with persistent stress urinary incontinence in the monopolar TURP group. Long-term complications were not statistically different between the groups.

De Sio *et al*. randomized 70 patients to treatment with Gyrus PK BiTURP or monopolar TURP and reported 12-month results [12]. Like the groups before, they found a decreased mean catheter time (100 h for monopolar TURP v 72 h for BiTURP) and mean length of stay (107 h for monopolar TURP vs 78 h for BiTURP) in the BiTURP group. No difference was found between the groups in 12-month IPSS, Qmax, or PVR: IPSS decreased from 20 preoperatively to 4 at 12-month follow-up in both groups; Qmax improved from roughly 5 mL/s preoperatively to 20 mL/s at 12-month follow-up in both groups; and PVR decreased from roughly 80 mL preoperatively to roughly 20 mL at 12-month follow-up in both groups. These authors noted no significant difference in adverse events.

Seckiner *et al*. similarly performed a randomized study comparing Gyrus PK BiTURP to monopolar TURP [13]. These authors compared 24 patients in each group and followed them for 12 months. There was no significant difference in operative and perioperative data, except for decreased serum sodium in the monopolar TURP group, with two patients in this group exhibiting mild dilutional hyponatremia. Like previous authors, these authors reported significant improvements in IPSS, Qmax, and PVR in both groups compared to baseline values but did not show any difference between groups.

Ho *et al.* performed a randomized study comparing Olympus TURis BiTURP (48 patients) to standard monopolar TURP (52 patients) and followed these patients for 12 months [14]. No differences in resection time or resection weight were noted. These authors did note significant decrease in serum sodium in the monopolar TURP group compared to the BiTURP group, with two cases of clinically significant dilutional hyponatremia in the former but none in the latter. Urethral strictures were observed in three of 48 patients in the BiTURP group and one of 52 patients in the TURP group. These authors also showed significant improvements in IPSS and Qmax at 12 months from baseline in both groups but no differences between groups. These authors concluded that monopolar TURP and BiTURP were equally efficacious, with BiTURP having a better safety profile.

Iori *et al*. performed a clinical and urodynamic evaluation of 51 patients with urodynamically proven bladder outlet obstruction and randomized to monopolar TURP (26 patients) or to BiTURP (27 patients) [15]. Mean follow-up was 12 months. There was no difference in resection time, catheterization time, or length of stay between the groups, or in change in serum hemoglobin or serum sodium. Of note, all patients underwent urodynamic evaluation prior to the procedure and at 12 months postoperatively. The Schaefer obstruction class was significantly improved after both procedures and as with other parameters, there was no difference in the urodynamic effects after monopolar TURP and BiTURP.

Michielsen *et al*. performed a large randomized trial comparing conventional monopolar TURP (120 patients) to Olympus TURis BiTURP (118 patients) [16]. These authors focused on intraoperative parameters and immediate perioperative morbidity. They noted no difference is resected prostate tissue weight and duration of hospitalization between groups. They did note that BiTURP took longer to perform, but that decrease in serum sodium was significantly greater for the monopolar TURP group. There was one case of TUR syndrome in the monopolar TURP group and none in the BiTURP cohort.

BiTURP has been reported to be a safe alternative to monopolar TURP for use in resident teaching and for the management of large-volume prostates. Bhansali *et al*. performed a randomized trial of 70 patients with prostate sizes greater than 60 g, comparing Gyrus PK BiTURP to monopolar TURP [17]. They noted no differences in length of stay or function outcomes at 9 and 12 months postoperatively between the two cohorts. They did notice significantly more blood loss, significantly longer catheterization time, and significantly larger changes in serum sodium in the monopolar TURP group compared to the BiTURP group. The authors concluded that it is safe to perform BiTURP in large-volume prostates.

Gilleran *et al*. commented on using BiTURP in an academic setting to help teach residents how to perform an adequate TURP [18]. These authors reported results of a series of 21 men who underwent Gyrus PK TURP in an academic setting. They noted that despite small size prostates (median resected tissue weight 20 g), the median resection time was 65 min, which is much longer than would be expected for the amount of tissue resected. While they did note a significant decrease in serum hemoglobin between preoperative and postoperative values, they did not report a significant difference in serum sodium and no patients needed blood transfusions. The authors concluded that BiTURP is a safe modality for resident medical education.

Large series of BiTURP have been reported recently. Martis *et al*. reported their series of 401 patients who underwent Gyrus PK BiTURP and noted no intraoperative complications [19]. They reported excellent and durable functional results measured by IPSS and Qmax through 36 months of follow-up. Three patients developed urethral strictures that were effectively managed with internal urethrotomy. Puppo *et al*. reported outcomes and complications after the first 1000 cases of Olympus TURis system resection, including 376 BiTURPs [20]. Other procedures using the saline bipolar technology in this report were 480 bladder tumor resections and 144 transurethral incisions of the prostate. The authors noted no cases of TUR syndrome and operative and function results better than in comparable series of monopolar TURP.

Mamoulokis *et al*. recently reported a systematic review and meta-analysis of all randomized control trial of BiTURP [21]. A total of 16 randomized controlled trial with 1406 patients which were included in the meta-analysis. The authors noted that efficacy of BiTURP was comparable to monopolar TURP, with respect to IPSS and quality-of-life metrics. However, Qmax was significantly improved with BiTURP over monopolar TURP at 12 months. This was weighted by one trial which showed marked improvements for BiTURP over monopolar TURP. The meta-analysis also evaluated decreases in serum sodium and incidences of TUR syndrome. There was a significantly larger difference in serum sodium decrease in patients undergoing monopolar TURP compared to BiTURP. Of note, while none of the individual studies showed a difference in the incidence of TUR syndrome, the pooled analysis did detect a significantly higher rate of TUR syndrome in patients who underwent a monopolar TURP compared to a BiTURP. The number needed to treat to prevent one case of TUR syndrome was 50.

Morbidity/complications

BiTURP appears to be safer than monopolar TURP, especially with regards to decreases in serum sodium and incidence of dilutional hyponatremia. All studies that report on serum sodium show a decrease and the meta-analysis performed by Mamoulokis *et al*. confirmed that serum sodium decreases and incidence of TUR syndrome are both significantly higher in monopolar TURP arms as compared to BiTURP arms [21]. BiTURP has not been compared to other prostate ablation modalities such as laser prostatectomy that also use normal saline as an irrigant.

Urethral strictures were noted to be higher in the early BiTURP studies, particularly in the study by Tefekli *et al*. that evaluated a hybrid vaporization/resection technique using Gyrus equipment [22]. These authors compared their saline bipolar technique to monopolar TURP and noted similar efficacy but a significantly higher rate of urethral strictures in the bipolar cohort. Other authors have suggested that the large cystoscope needed to perform continuous flow BiTURP and possibly longer operative times may be associated with an increased incidence of urethral strictures [16]. A unique aspect of Olympus TURis BiTURP has also been implicated; the fact that current returns through the inner sheath [14]. An equipment malfunction could potentially expose the urethra to active current, potentially leading to urethral strictures. Despite the fact that the cutting loops for TURis are single use, some authors have speculated that reusing the loops leads to a higher stricture rate. The pooled analysis of all BiTURP randomized control trials has not shown a higher rate of urethral stricture and in fact shows comparable stricture and bladder neck contracture rates with BiTURP and monopolar TURP [21].

The perception of increased intraoperative and postoperative blood loss with BiTURP remains controversial. While early reports of coagulation zone after saline bipolar resection showed a smaller zone of coagulation than monopolar TURP [23], more recent report have shown a larger zone [24] and others have shown differences in size of zone measured immediately postoperatively and that measured a few days postoperatively [25]. It remains unclear whether decreased or increased zone of coagulation is beneficial as far as hematuria. Regardless, the pooled meta-analysis showed no difference in intraoperative or postoperative blood loss following BiTURP compared to monopolar TURP [21].

Cost

The cost of BiTURP is an important consideration, especially with pressures on most healthcare systems to control cost of healthcare. The Urologic Diseases in America project estimated that over US$1 billion was spent in the USA on the management of BPH, not including costs of medicines [3]. It appears that BiTURP may be less expensive than monopolar TURP despite increased capital costs and increased disposable costs. This has been postulated to be because of potential decreased length of stay and possibly decreased postoperative complications with BiTURP. BiTURP has not been compared to other modalities for prostate debulking, but is likely to be at least competitive with these. The fact that BiTURP is a technique that most urologists have learned in graduate medical education may decrease the training costs associated with learning newer techniques such as laser prostatectomy. However, these new modalities may offer similar improvements in length of stay and morbidity as compared to BiTURP, just as BiTURP has done compared to monopolar TURP.

Whether the differential in these recurring costs is greater than initial capital outlay remains to be seen.

Education issues

BiTURP has been touted as a useful adjunct for urology graduate medical education [6, 18], due to the decreased risk of dilutional hyponatremia and therefore more time available for resident operative teaching. While this is valid, it should be noted that the number of TURPs, monopolar or bipolar, has been declining for decades [3]. In fact, over a 7-year period during which BiTURP was available, graduating chief residents performed approximately 25% fewer cases [26]. This might be due to an increase in other ablative treatments such as laser prostatectomy and may be a reversible trend if BiTURP is adopted by the urologic community.

A more fundamental question is the role of TURP in the management of BPH/LUTS. With the advent of effective medical therapy and availability of a host of other ablative and minimally invasive techniques for the surgical management of BPH/LUTS, the TURP procedure may be performed less and less often and therefore may not remain the "gold standard." If this were to happen, some of the advantages of BiTURP may be less obvious.

Conclusions

BiTURP is an effective modality for the surgical management of BPH/LUTS. It has been in use for only about a decade and during that time it has demonstrated efficacy similar to monopolar TURP with a potentially improved safety profile. It has not been compared to other transurethral ablative therapies for the prostate that use saline as an irrigant. If TURP remains the "gold standard" for surgical management of BPH/LUTS in the future, then BiTURP will continue to have an increasing role.

CHAPTER 134
Bipolar Vaporization of the Prostate

Kyle A. Richards & Gopal H. Badlani
Wake Forest University Baptist Medical Center, Department of Urology, Winston-Salem, NC, USA

Introduction

Transurethral resection of the prostate (TURP) has long been accepted as the gold standard surgical treatment of benign prostatic hyperplasia (BPH). It is the measuring stick for all other minimally invasive treatments for BPH as traditional TURP is highly effective in improving urinary flow rates and decreasing symptom scores; the Agency for Health Care Policy and Research (AHCPR) panel guideline meta-analysis showed that patients had an 88% chance of symptomatic improvement after TURP [1]. However, due to the morbidity associated with monopolar TURP, including the risk of bleeding, clot retention, impotence, urethral stricture, and transurethral resection (TUR) syndrome, as well as the length of hospitalization and catheterization, urologists have been tinkering with other minimally invasive treatments for BPH for decades.

Vaporization of the prostate was first described in the early 1990s using either conventional electrical surgery, termed electrovaporization, or laser techniques [2]. Subsequently, transurethral vaporization of the prostate (TUVP) was first described by Kaplan *et al*. in 1995 [3]. The proposed advantages of TUVP included less blood loss, shorter catheterization time, and shorter hospitalization, all the while maintaining efficacy. Initially, electrovaporization techniques were performed using monopolar currents. Monopolar current has its own associated problems. First, the use of a conductive irrigant is required, such as glycine or mannitol, which may result in systemic absorption of hypotonic fluids, thus risking hyponatremia and TUR syndrome. Second, the patient is part of an electrical circuit that can pose a risk for patients with pacemakers and cause diathermy burns at the site of the return plate. Third, monopolar current does not allow simultaneous cutting and coagulation. Therefore, bipolar electrocircuitry was developed for minimally invasive prostate surgery to address some of the aforementioned issues. Bipolar vaporization or resection allows normal saline to be used, which is isotonic, avoids the need for a return plate as the patient is not part of the electrical circuit, and allows simultaneous cutting and coagulation.

Bipolar electrovaporization of the prostate was first described in 2001 using a Gyrus device [4]. Since then, numerous centers have reported level 1 evidence for favorable short-term outcomes using bipolar vaporization of the prostate. Herein we present a review of the mechanism of action of bipolar vaporization, various electrode and generator designs, clinical experience, and relevant comparative studies.

Mechanism of action

Vaporization is produced via the application of energy to the prostate, which results in heating of the tissues. The tissues are primarily composed of intracellular water, which subsequently boils at a rapid rate, thus producing steam. This results in cellular disruption and tissue destruction, thus leaving a void where the cells were previously present. In electrosurgery, the rate of electrical energy delivered is measured in watts (W), current (I) flows through the tissue, and the tissue creates electrical impedance (R). Heat is created due to

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

the electrical impedance of the prostate to current flow, therefore:

$$W = I^2R$$

Most of the energy delivered to the prostate results in vaporization of the surface layer of cells; however, some of the energy has been shown to disperse below the vaporization layer to create a zone of coagulation, resulting in improved hemostasis. This phenomenon of simultaneous vaporization/ablation and coagulation is the principal benefit of TUVP techniques. The actual depth of coagulation depends on system and electrode design. The technique employed by the surgeon will also impact the depth of coagulation as this is increased by increased pressure on and time in contact with the tissue. Importantly, coagulation has to take place with bipolar technology at lower peak voltages compared to monopolar surgery [80–100 V for the PlasmaKinetic (PK) system] as higher voltages will convert the liquid into a gaseous phase, resulting in higher impedance. The impedance therefore is changed from a resistive to a capacitative mode, thus reducing energy flow, dissipating heat, and decreasing the final coagulation effect.

In bipolar and monopolar cutting, the generator must initiate a momentary high-energy spike to initiate a plasma vapor layer. This layer is ionized in the form of a nonequilibrium plasma, where plasma ions and electrons are responsible for current flow. In monopolar circuitry, the current arcs to the tissue and passes through the patient to a large surface return electrode on the skin heating the intervening tissue by ohmic resistance. However, in bipolar surgery, the active and return electrodes are in close proximity to each other, separated by an insulator. The electron emission from the smaller active electrode heats and vaporizes the adjacent intracellular water to form a thin gas layer (plasma pocket) that grows and forms a larger bubble containing energetic species that can dissociate both water and organic molecules, resulting in the net tissue effect [5]. It is likely that the thermal effect noted with bipolar surgery takes place at much lower temperatures (<70°C) compared to monopolar surgery (300–400°C). Once the plasma vapor pocket is formed, it can be maintained at low voltages (100–350 Vrms) as the electrode is close to making contact with the tissue. Tissue destruction ensues due to the breakdown of carbon–carbon and carbon–nitrogen bonds. This results in the production of elementary molecules and low molecular weight gases, including carbon dioxide, oxygen, nitrogen, and hydrogen. Intraoperatively, the effect is precise cutting and vaporization with minimal collateral damage as the charged sodium ions contained within the plasma vapor pocket have only a short estimated range of penetration (50–100 μm). This is largely due to electrosurgical principles as minimization of collateral tissue damage is dependent upon resistive heating caused by any current flowing through tissue and by limiting thermal transfer from the electrode sources. The final result in the human prostate is precision tissue cutting/vaporization with minimal charring and burnt prostate odor traditionally equated with monopolar TURP.

Specialized generators were developed along with the bipolar technology using radiofrequency (RF) energy output. The initial bipolar vaporization of the prostate used a Gyrus device and generator designed with a 200-W capability with an RF range of 320–450 kHz and a voltage range of 254–350 V [4]. However, the Vista Coblation system (ACMI Corporation, Southborough, MA, USA) used RF energy output from a specialized electrosurgical generator that is one-fifth that of monopolar generators (100-kHz square wave) [6]. The initial Olympus SurgMaster generated an RF output of 350 kHz and a recent report used the UES-40 SurgMaster (Olympus Winter & Ibe GmbH, Hamburg, Germany) with a power output of 290 W and 120 W for vaporization and coagulation, respectively (Figure 134.1) [7]. The frequency of the newest system from Karl Storz (Autocon® II 400 Electrosurgical System; Tuttlingen, Germany) (Figure 134.2) generates an RF output of 350 kHz with a power output of 120 W for coagulation.

Electrode and generator design

The bipolar technology was developed with the active and return electrodes in close proximity to one another, separated by an insulator. Energy from the generator travels through the active electrode, through the plasma pocket, through the conductive solution to the tissue bed, and returns via a thicker electrode to the active cord to the ground. Hence, there is no need for any energy to travel through the patient to a return electrode on the skin, eliminating the risk for inadvertent burns from inadequate contact. Also, the low operating frequency and voltage of bipolar surgery should eliminate any potential for interference with cardiac pacemakers.

There are several challenges to electrode design, including establishment of a reliable plasma corona preferentially at the distal active electrode, to achieve a plasma condition with short delays from the time of foot-switch activation by the surgeon, to provide adequate hemostasis from both cut and coagulation sources of foot-switch operation, and to maintain this under all surgical conditions. With these challenges in mind, manufacturers and urologists are still in search of the "ideal" electrode for bipolar TUVP. The commercially available electrodes vary in size and configuration; however, in general, the active component is slightly thinner and separated by the thicker return electrode component by an insulator. The commercially available systems also vary in terms of resectoscope sizes, design of electrode housings, and coupling mechanism between active and return cords.

The PK® Gyrus system was the first bipolar vaporization technology reported in the literature and therefore had to address several of these early technical issues. For bipolar vaporization to occur, at the time of foot-pedal activation, the active electrode must be in close proximity to the tissue because if the gap is too wide or if there is insufficient power, current flow is dissipated by the large volume of electrolyte solution in a full bladder and there is no effect on the tissue. Furthermore, if the power/voltage spike is not great enough to maintain the plasma pocket, cutting and vaporization of the tissue will occur in a stuttering fashion, depending on the quality of tissue contact.

With these limitations and challenges in mind, the initial PK® Gyrus system was modified, resulting in a second-generation model called the PK® SuperPulse® Generator. There are several advantages of this system. First, this device is preconfigured for maximal allowable current under low impedance conditions. Second, the surgeon can choose between two sets of preset cutting voltages. Third, the generator is designed to recognize the active electrode offering default settings that are optimal for a wide range of conditions at the tip. Lastly, the PK SuperPulse generator is equipped with a row of internal capacitors acting as an energy reservoir to ensure sufficient voltage for instantaneous fire-up and for power ride-through under challenging conditions of impedance. These modifications have resolved the issue of stuttering cutting/vaporization that occurred previously. The capacitor reservoir can provide up to 4000 W of power for short periods of time (10 ms) if the tip impedance is low enough. This may be important because under conditions of high flow with cold saline, more power than normal is required to create and maintain the initial plasma pocket at the active electrode tip.

At baseline, prior to RF voltage application, the impedance differential between bipolar active and return electrodes is between 23 and 60 ohm with variability due to the irrigation temperature and the proximity of the active electrode to the tissue bed. The PK SuperPulse generator can generate a high enough power (4000 W) at low impedance (23 ohm) to sustain a voltage of close to 300 Vrms that boils the saline immediately surrounding the active loop in a matter of milliseconds. This phenomenon is largely due to the electrode design. The electrical current crowds at the reduced surface area of the active electrode, resulting in a nonequilibrium vapor pocket containing charged sodium ions. The activated sodium ions form the plasma inside the vapor pocket and produce the orange glow that is visible to the naked eye. There is a time delay of 1–2 μs from the initial negative current spike until light is emitted. Once the plasma is formed, the impedance increases greatly from 500 to 3000 ohm, depending on whether the electrode is in contact with the vapor pocket versus the irrigant, and or the length of the vapor pocket (as there is a higher impedance with longer plasma vapor pocket lengths). The power delivery now becomes focused around the active electrode and is not dissipated in the surrounding saline solution and prostate tissue, and therefore much less power is required to sustain the plasma vapor pocket. The energy reservoir can then be replenished as the output voltage falls by being repeatedly formed during each half cycle of the high-frequency exciting voltage waveform.

The PK SuperPulse generator has two sets of preset cutting voltages (termed SP1 and SP2). At the lower preset voltage of SP1, plasma volume is smaller and impedance is lower, and detected intraoperatively as a less intense orange glow around the active electrode. The SP2 setting can be used during suboptimal operative conditions when cutting/vaporization becomes difficult, to allow for an increased plasma volume and slightly higher preset voltage. Foot-pedal activation and fire-up should take no longer than 20 ms as a result of the energy reservoir of the internal capacitors. Once an activated electrode is in contact with tissue, *in vivo* studies have demonstrated that no more than 100 W are

usually required to sustain the user-defined maximum voltages.

Clinical experience

Bipolar TUVP has been in clinical use for a decade. The initial experience was reported in 2001 by Botto *et al.* using the Gyrus device and a rolling-type electrode (Axipolair®) [4]. This pilot study utilized the first-generation PK Gyrus generator and the electrode consisted of an active component (manufactured from 80/20 platinum/iridium alloy) and a return electrode (manufactured from stainless steel) placed on the same axis. A ceramic insulator separated the active and return electrodes. The initial technique describes vaporizing the obstructing tissue by placing the electrode in direct contact with the prostate in a systematic fashion similar to the technique for traditional TURP. The two major differences in performing bipolar TUVP include modeling the prostatic cavity in a circumferential action and the need to activate the current prior to bringing the electrode into direct contact with the tissue to allow the vapor pocket to build up. Therefore, for experienced endoscopists, the learning curve for bipolar TUVP is quite minimal. Forty-two patients with symptomatic BPH were included in this study and underwent bipolar TUVP using a standard 27F resectoscope sheath and normal saline as irrigant. A majority of the patients (19) had a prostate volume between 30 and 60 mL and 93% of the operations took less than 60 min to complete. The mean postoperative hospitalization (including the day of surgery) was 2.2 days and all patients passed a voiding trial prior to discharge home. Early complications included bulbar urethral stricture in two patients requiring endoscopic urethrotomy, and dysuria in four patients, two of whom complained of dysuria for 3 months. Functional outcomes were assessed with International Prostate Symptom Score (IPSS) and maximum flow rate (Qmax) at baseline and at 3 months. Mean IPSS decreased from 19 to 9 and mean Qmax increased from 7.9 mL/s at baseline to 19.7 mL/s at 3 months. These early clinical results showed feasibility, safety, and acceptable short-term outcomes that warranted further study.

Eaton and Francis performed bipolar TUVP in 40 patients with BPH symptomatology in a day surgical unit setting in the UK [8]. Similarly, bipolar TUVP was carried out using the Gyrus PK tissue management system (Gyrus Medical Ltd, Buckinghamshire, UK), which involved a 27F continuous flow resectoscope sheath and normal saline irrigation. The mean operative time was 33 min (range 12–52 min) and mean prostate volume was 34.9 mL (range 15–76 mL). No patients had any electrolyte abnormalities or significant drop in hemoglobin level postoperatively. All but six patients were discharged home on the day of surgery, with an average hospital stay of 5.9 h. All patients voided successfully at 48 h, but two returned with obstructed catheters, thought to be due to coagulum and not blood clot or tissue fragments. At 4 months there was an improvement in IPSS and quality of life by 64% and 83%, respectively, and an improvement in mean flow rate of 200%, but no baseline data were reported in any of these categories.

Dincel *et al*. reported on their initial experience with bipolar TUVP using the Gyrus PK tissue management system and a Plasma-V™ electrode (Figure 134.3) [9]. Twenty-one men with moderate-to-severe lower urinary tract symptoms (LUTS) attributable to BPH underwent bipolar TUVP, of whom 20 returned for follow-up and were available for final analysis. The median prostate volume was 42 mL and the operative time increased as the size of the prostate increased (median 55 min). The median duration of catheterization and time to discharge was 3 days. The only perioperative complication reported was constipation in one patient who required readmission due to clot retention and was transfused two units of blood. Median IPSS and urine flow rates were significantly better at 90 days postoperatively, and postvoid residual urine volume (PVR) had significantly decreased from a median of 54 mL to 19.5 mL. Serum PSA values were measured preoperatively, postoperative day 1, 30 days postoperatively, and 90 days postoperatively. Serum prostate-specific antigen (PSA) values were significantly increased on postoperative day 1, and then trended back towards preoperative levels by 90 days postoperatively, prompting the authors to suggest that serum PSA levels should not be obtained in patients who have undergone bipolar TUVP until at least 30 days postoperatively. Furthermore, in these early studies, patients were heavily screened preoperatively for prostate cancer with serum PSA measurements and digital rectal examination (DRE), as it is important to note that no tissue is retrieved from TUVP for pathologic analysis. Therefore, patients with abnormal PSA/DRE were excluded from participation in these studies. While the results of these nonrandomized clinical trials were promising and sparked the interest of the urologic community, large randomized prospective trials with long-term follow-up were needed to provide better evidence-based medicine rationale for the use of this new technology.

Comparative studies

In 2003, Dunsmuir *et al.* reported the first randomized prospective clinical trial comparing bipolar TUVP to traditional monopolar TURP [10]. This study randomized 51 men with LUTS secondary to BPH to bipolar TUVP ($n = 30$) versus monopolar TURP ($n = 21$), of

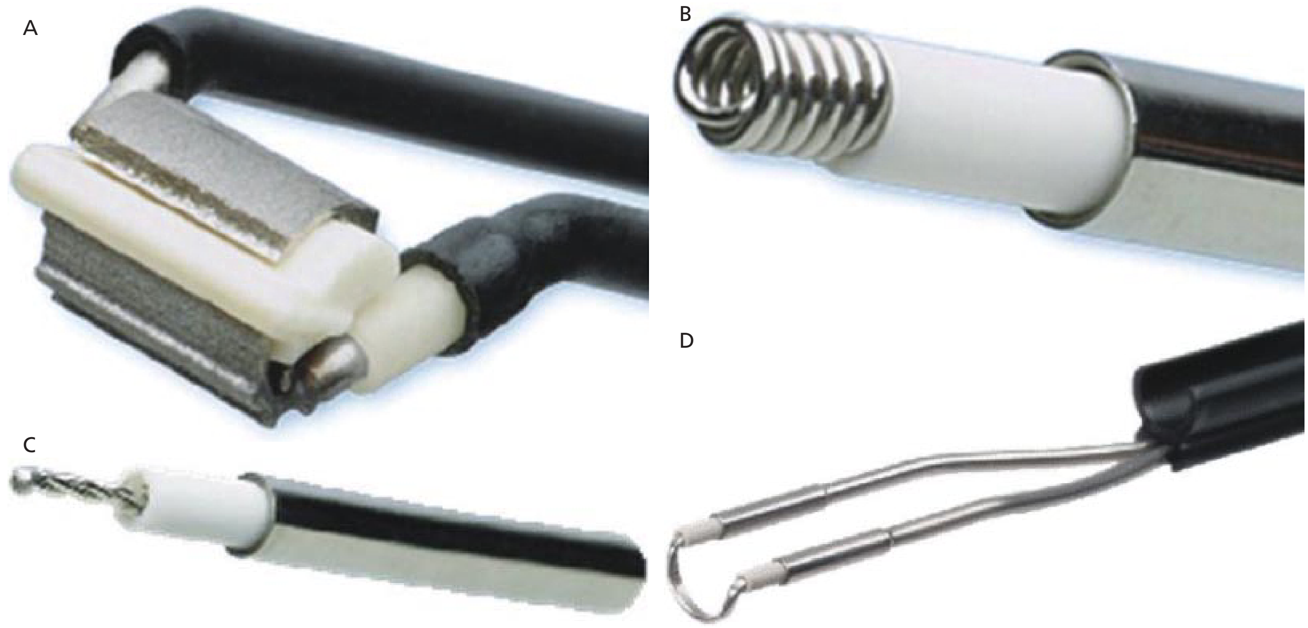

Figure 134.3 (A) PK ® Plasma-V PK "SuperPulse" Generator Vaporization Electrode (Gyrus, ACMI, Southborough, MA, USA), (B) PK PlasmaCise PK "SuperPulse" Generator Electrode (Gyrus, ACMI), (C)PK ® PlasmaCut PK "SuperPulse" Generator Electrode (Gyrus, ACMI), (D) PK SuperSect (Wider Surface Loop) Generator Electrode (Gyrus, ACMI). (Reproduced by permission of Olympus.)

which 40 (20 in each group) completed follow-up at 1 year. The bipolar TUVP arm underwent vaporization using a similar technique to that previously described using the Gyrus PK device with the Axipolaire electrode, and monopolar TURP was performed using standard techniques. In terms of perioperative outcomes, there was no difference in operative time, irrigation time, time to catheter removal, or length of hospital stay between the two groups. These patients were followed up 1-year later and improvements in IPSS, flow rates, PVR, and quality of life were similar between the two groups. Interestingly, four patients in the TURP group compared to zero patients undergoing TUVP required manual clot evacuation in the postoperative period, but the recatheterization rate for the TUVP procedure was 30% (compared to 5% for traditional TURP). All patients voided successfully 2–3 weeks later (range 14–19 days).

Hon *et al*. performed a randomized prospective clinical trial on 160 consecutive patients in their practice undergoing transurethral prostatectomy for bladder outlet obstruction [11]. They randomized the men to traditional TURP (n = 81) versus bipolar TUVP (n = 79) using the Gyrus PK system and the Plasma-V bar electrode. The two groups were similar preoperatively in regards to baseline characteristics. Mean operative time was 4 min shorter in the TURP arm, but this was not statistically significant (28.5 vs 32.6 min, $P = .08$). There was no significant difference between the two groups with respect to intraoperative blood loss; however, the TURP group had a greater hemoglobin decrease postoperatively (1.4 vs 0.8 g/dL, $P = .002$). Likewise, the TURP patients required more irrigant (28.3 vs 20.1 L, $P = .001$) and more manual bladder irrigations postoperatively (31 in 11 patients compared to 11 in seven patients who underwent TUVP, $P = .27$). The only difference in short-term adverse events included a total of 14 units of blood transfusion in the TURP arm compared to zero units of blood transfusion in the TUVP arm. The hospital stay was significantly longer for patients who underwent TURP compared to TUVP (3.4 vs 3.0 days, $P = .04$). Interestingly, despite rigorous preoperative screening, eight patients in the TURP arm were found to have prostate carcinoma detected on prostate chip histology. Long-term outcomes were available in 93% of the patients at a mean follow-up of 258 days. IPSS, quality of life, PVR, and Qmax improved significantly regardless of technique; however, there was no statistically significant difference detected in any of these categories other than for average urine flow when comparing TURP to bipolar TUVP. This fairly large trial with a decent length of follow-up concluded that bipolar TUVP has equivalent outcomes to monopolar TURP but with fewer earlier complications.

The disadvantage of bipolar TUVP is the lack of tissue for histologic processing. It is important to note that some clinically significant cancers may be missed, therefore highlighting the importance of screening these patients preoperatively and following them postoperatively with serial serum PSA and DRE.

Due to the potential for missing cancer and lack of tissue obtained from pure vaporization techniques, researchers began exploring a possible hybrid technique. This technique combined bipolar vaporization of the prostate with bipolar resection (TUVRP) and was described by Tefekli *et al.* in 2005 [12]. It should be pointed out that other researchers have shown that tissue sampling with a resection loop after vaporization of the prostate may not increase the likelihood of cancer detection [13]. In this randomized prospective clinical trial, 50 patients undergoing surgery for BPH were randomized to standard monopolar TURP and 51 patients were randomized to the hybrid bipolar TUVRP technique. The bipolar TUVRP procedure was performed with the Gyrus PK system using saline for irrigation. The lateral and median lobes were removed with a vaporization electrode and the final resection of tissue tags and apical tissue around the verumontanum were removed with a resecting loop. This technique was employed to not only remove tissue for pathologic analysis but also to aid delicate tissue resection around the apex and verumontanum. Complete data were available on 96 patients with a mean follow-up of 18.3 months (range 12–23 months). Mean operative time, catheterization time, and hospital stay were significantly lower in the TUVRP group compared to the TURP group. Mean improvement in Qmax was significantly better in the TUVRP group at 12 months, but mean improvement in IPSS from baseline was equivalent between the two groups. However, these authors did note an increase in irritative symptoms and recatheterizations in the TUVRP group, which they hypothesized was due to increased tissue edema due to the higher current with lower frequency exerted on the tissue. Of the three patients in the TUVRP group who required recatheterization, all were able to void after 7 days. The increased recatheterization rate paralleled the findings of Dunsmuir *et al*. [10]. Urethral stricture was also a more common complication in the TUVRP group (three TUVRP vs one TURP, $P = .002$) and was successfully managed endoscopically in all patients. The reoperation rate for persistent obstructive symptoms was not statistically significant, likely due to the low number of events in each group, with two patients in the TUVRP arm and only one in the monopolar TURP arm.

With several randomized prospective clinical trials emerging in the literature comparing bipolar TUVP to monopolar TURP, Neill *et al.* elected to compare holmium laser enucleation of the prostate (HoLEP) to bipolar TUVP in a randomized prospective clinical trial [14]. Forty patients were randomized 1:1 to either HoLEP or bipolar TUVP using the Gyrus PK device with the Axipolaire electrode. In their study, HoLEP performed better than TUVP in regards to mean operative times (43.6 min vs 60.5 min, $P < .05$) and fewer patients in the HoLEP arm required bladder irrigation (5% vs 35%, $P < .001$). The other outcomes analyzed, including hospital stay, catheterization time, complication rate, changes in IPSS, and maximum flow rate at 12-month follow-up, were all similar between the two groups. These authors concluded that bipolar TUVP has equivalent functional outcomes to HoLEP but increased intraoperative bleeding, which results in longer operative times and increased postoperative irrigation requirement. Surgeon preference, bias, and familiarity also play a large role and may have influenced these investigators to those conclusions.

Figure 134.4 Bipolar mushroom-like electrode (reproduced by permission of Olympus Winter & Ibe GmbH, Hamburg, Germany).

As solid level 1 evidence showing the safety and efficacy of bipolar TUVP has mounted, investigators have continued to search for the optimal electrode for bipolar vaporization. Recently, Reich *et al*. reported on a novel mushroom-like electrode (Olympus Winter & Ibe GmbH) [7]. This pilot study utilized the UES-40 SurgMaster (Olympus Winter & Ibe GmbH) bipolar high-frequency generator, a 26F continuous flow resectoscope, normal saline as irrigant, and the aforementioned electrode (Figure 134.4). The vaporization technique is performed using the electrode in a near-contact technique (so-called *hoovering* technique). The procedure is otherwise performed like a traditional TURP, making the learning curve minimal (see Video 134.1). Thirty patients with BPH underwent bipolar TUVP using the mushroom-like electrode. The mean prostate volume was 59 mL (range 30–170 mL) and mean operative time was 61 min (range 20–140 min). No perioperative complications were noted, no patient required a blood transfusion, and no postoperative electrolyte abnormalities were noted. Postoperatively, four patients (13%) required recatheterization and the mean catheterization time was 41 h (range 18–192 h). Around half of the patients (53%) required continuous bladder irrigation postoperatively. The reoperation rate at 6-month follow-up was 3% (one patient required traditional TURP due to persistent obstructive symptoms). Transient mild-to-moderate dysuria was present in four patients (13%) and resolved within 2 weeks postoperatively with anti-inflammatory agents. Functional outcomes assessed at 6 months compared to baseline were excellent. Mean

Qmax increased from 6.6 mL/s at baseline to 18.1 mL/s at 6 months ($P < .01$). Mean IPSS decreased from 20.8 at baseline to 8.1 at 6 months ($P < .01$) and mean PVR decreased from 165 mL at baseline to 38 mL at 6 months ($P < .01$). This recently reported pilot study shows feasibility and acceptable short-term outcomes utilizing this novel electrode, and randomized prospective trials comparing this device to traditional monopolar TURP are underway.

Conclusions

Bipolar TUVP has been shown to be a safe and effective treatment for BPH through several well-performed randomized prospective clinical trials. Clearly, larger multicenter trials are needed with longer-term follow-up to assess long-term outcomes, specifically the reoperation rate and rate of urethral stricture occurrence. Certainly there is a role for bipolar TUVP in the toolbox of treatments available for BPH as urologists tackle larger prostate glands endoscopically and operate on sicker patients. Whether bipolar TUVP becomes widely accepted remains to be determined, especially in the face of stiff competition from high-powered lasers (holmium and KTP).

CHAPTER 135

Single-Port Transvesical Simple Prostatectomy

Rene Sotelo, Camilo Giedelman & Mihir Desai

History

Open surgery has traditionally been the treatment of choice for benign, symptomatic prostatomegaly [1]. More than 2000 years ago, surgeons began using a median perineal incision for the removal of bladder calculi and in the first century of the classical era, surgeons used a semi-elliptical incision in this same perineal location for partial removal of the prostate. Although there are infrequent records documenting its use for a few hundred years, this perineal approach continued to be applied until 1894 when Eugene Fuller performed the first suprapubic prostatectomy. It was not until 1912, however, that the procedure was popularized as a result of Peter Freyer reporting his results with this technique, which consisted of the enucleation of the hypertrophic prostatic adenoma through an extraperitoneal incision of the lower anterior bladder wall. The next transition in surgical approach for treating benign prostatic hyperplasia (BPH) occurred over 30 years later, in 1945, when the retropubic simple prostatectomy was first described by Terence Millin. In 20 patients he reported a technique by which he achieved complete enucleation of the prostatic adenoma through a transverse capsulotomy incision on the anterior surface of the prostate gland. Subsequently, transurethral endoscopic techniques have virtually replaced the open approach in the surgical management of the majority of cases of BPH [2].

Recent developments in laparoscopic simple prostatectomy

Currently, despite the development of transurethral surgery and new technologies employed with this access, open surgery continues to be the ideal treatment for large adenomas in terms of its cost-effectiveness for this pathology. Modifications of the gold-standard transurethral resection have been incorporated into clinical practice and include bipolar transurethral resection, as well as holmium laser resection and potassium titanyl phosphate (KTP) laser vaporization. Minimally invasive ablative techniques have also been popularized and include transurethral needle ablation and thermotherapy [2].

Over the last decade, with the advent of laparoscopic and robotic surgery, new treatment alternatives have also begun to be used. In 2002, Mariano *et al.* described a technique for laparoscopic simple prostatectomy [3], which was reproduced with some modifications and then performed with robotic assistance. This basically duplicates the techniques of open surgery and maintains the standard of open surgery in regard to the proportion of tissue extracted, but with all the benefits associated with this type of minimally invasive surgery [4, 5].

Given that the ease of implementation of natural orifice transumbilical endoscopic surgery (NOTES) surgery is currently limited by the technologic equipment available, an intermediate alternative has been suggested in an attempt to further reduce the morbidity of laparoscopic surgery and improve its cosmetic results. This alternative is the use of a single access point into the abdominal cavity through the umbilical scar. This approach has been given different names, including E-NOTES (embryonic natural orifice transumbilical endoscopic surgery), NOTUS (natural orifice transumbilical surgery), SPA (single port access), and LESS surgery (laparoendoscopic single-site surgery). LESS is the use of endoscopic and laparoscopic techniques

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

through a unique small incision using a single device that allows for the introduction of various instruments [6]. We began to explore the possibilities of applying this new access method to our technique of laparoscopic simple prostatectomy, first through the umbilicus and later through a small suprapubic incision that is used to place the port directly into the bladder. The operation was developed as a collaboration between Drs Gill and Desai and our group. In this chapter, we will describe the technique in detail, highlighting tips that may be useful in performing the surgery. We will also discuss the results obtained up until this point.

Single-port transvesical enucleation of the prostate

LESS adenomectomy can be performed by placing a single-port device in the umbilicus with a transperitoneal approach. This is challenging, because the bladder must be dropped and the finger cannot be used to assist the enucleation. Additionally, at the end of surgery, the cystotomy incision has to be closed laparoscopically in a water-tight manner. With the new double-bend instruments, this method has been made easier, but it is still inherently difficult to carry out.

Another option is to place the port directly through the bladder (Figure 135.1). In this manner, the bladder does not need to be dropped. Also, the finger can be used to assist the enucleation. At the end of surgery, the cystotomy closure can be done in a standard open fashion.

The laparoendoscopic transvesical simple prostatectomy is performed through a small incision of 2.5–3 cm, located 3 cm from the pubic symphysis, through which the device (R-port, Triport) is directly inserted. This device has two particularly important qualities: first, is has multiple flexible valves that do not protrude into the cavity and allow introduction of curved instruments; and second its valvular component is easy to open and does not need to be taken out to be changed, a crucial aspect in intraluminal surgery. Increasing interest in LESS surgery has come with the introduction of new instruments, such as the 5-mm flexible EndoEye (videoscope (Olympus, Tokyo, Japan) with its excellent image, and flexible, curved instruments that permit laparoscopic dissection and intracorporeal suturing [7].

Indications and contraindications

Single-port transvesical enucleation of the prostate (STEP) is indicated for patients with large prostates of greater than 70 g, as evaluated by transurethral ultrasound (TRUS).

Absolute contraindications to STEP include the presence of prostate cancer, morbid obesity, anticoagulation therapy, and anesthetic contraindications. Relative contraindications include the need for concomitant procedures such as hernia repair and bladder diverticulectomy. Another relative contraindication is prostates larger than 200 g.

Preoperative preparation

Preoperative evaluation must include history and physical examination. Also, digital rectal examination and routine laboratory tests are required, including prostate-specific antigen (PSA), International Prostate Symptom Score (IPSS), quality-of-life (QoL) questionnaires, uro-

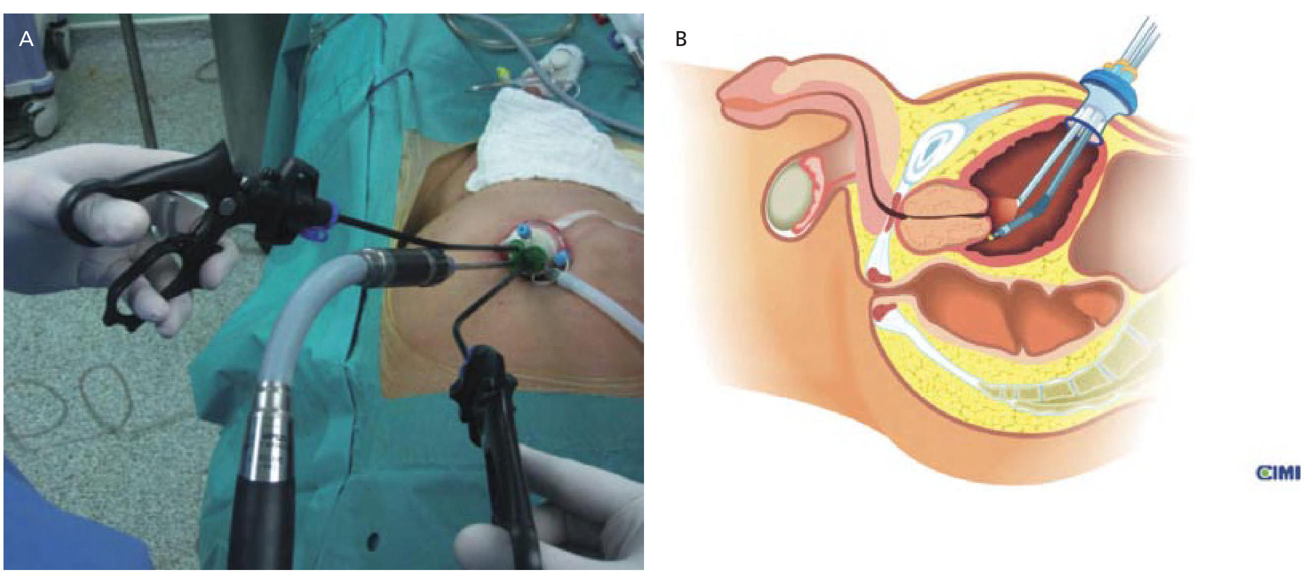

Figure 135.1 (A, B) Port placement directly through the bladder.

flowmetry, and TRUS evaluation of prostate volume and presence of the middle lobe. Urine should be cultured and preoperative antibiotics given. In cases where there is evidence of previous hematuria, acute urinary retention or urinary lithiasis, and cystocopy should be performed. Patients should stop taking Aspirin or any anticoagulant at least 8 days before surgery.

Surgical technique

The equipment and instruments required are listed in Table 135.1.

The Triport is a multiport access device that allows several instruments to pass simultaneously. It consists of a retractor and a valve. The retractor has an interior ring, two exterior rings, and a plastic retractable sleeve. The valve has three openings (two of 5 mm and one of 12 mm) for laparoscopic instruments and a port for inflation. The valve contains a thermoplastic elastomer that allows for the proper introduction of the instruments, including needles, with insignificant air loss.

Surgical steps

The advantages and disadvantages of this procedure are summarized in Table 135.2, and the key points in Table 135.3.

Table 135.1 Equipment and instruments required for single-port transvesical simple prostatectomy.

Equipment
Laparoscopic video tower (21-inch monitor, EXERA II image processor with light source)
Video laparoscope: EndoEye (Olympus, Tokyo, Japan), 5-mm, 30° lens
UHI-3 high-flow CO_2 inflator (up to 35 L/min).
Ultrasonic generator
Electrosurgical unit (monopolar/bipolar)
Aspiration–irrigation pump
Flexible cystoscope
Instruments to develop the procedure
Triport (Advanced Surgical Concepts, Wicklow, Ireland/Olympus).
5-mm flexible articulating instruments: scissors (Cambridge Endo, Framingham, MA, USA)
5-mm J hook electrocautery instrument
Ultrasonic 5-mm shears
5-mm suction–irrigation cannula, pre-bent
Carter–Thomason device
Two laparoscopic needle holders
Silicone three-way 22F and two-way 24F Foley catheters, in case a suprapubic tube is needed.
Sutures: Monocryl 0 with CT-1 needle for adenoma traction, and 2/0 with CT-1 needle for ligature of lateral pedicles and trigonization (the monofilament facilitates the extracorporeal knotting)
Sotelo prostatotomy device
Knot pushers

Table 135.2 Advantages and disadvantages of single-port transvesical simple prostatectomy.

Advantages
• Pneumovesicum maintains a broad field of work
• Allows the observation of all anatomic details of the bladder, prostate, and urethra during each step of the surgery.
• Lower risk of intestinal injury and lower likelihood of development of postoperative ileus
• Easy opening of the device allows the extraction of fragments during surgery. Furthermore, it allows the introduction of a finger if necessary to remove the adenoma
• Due to the fact that the adenoma fragments are confined in the bladder and are not released in the abdominal cavity, extraction pouches are not necessary
Disadvantages
• Steep learning curve. At first, enucleation is difficult, but the location of the suprapubic incision allows bimanual dissection if necessary. The index finger of the left hand in the rectum elevates the prostatic fossa and the index finger of the right hand through the ring of the Triport helps the mobilization of the adenoma

Table 135.3 Key points in the procedure.

• Placement of a traction suture through the full thickness of the bladder using absorbable material. The same stitch will enable placement of subsequent stitches, which will facilitate introduction of the trocar and the closure of the defect at the end of the case
• It is important to lubricate the entrance of the Triport in order to facilitate entry of instruments through the membranes, as well as facilitating the introduction of the videoscope and its rotational movement
• The incision should be made between the adenoma and the mucosa of the bladder. The surgeon can observe a faint change in color. This serves as a reassuring reference point
• If problems arise in the traction of the adenoma, the suture can be exteriorized through the abdominal wall with the assistance of a Carter–Thomason device
• A useful tool designed specifically for prostatic adenomectomy is the Sotelo prostatotomy device. This consists of three parts: a Teflon sleeve, a stainless steel cylinder body, and a curved shape with sharp edges at the distal end
• It is important to note that, if necessary, the surgeon can convert the procedure to a standard laparoscopic surgery with the addition of more trocars as necessary

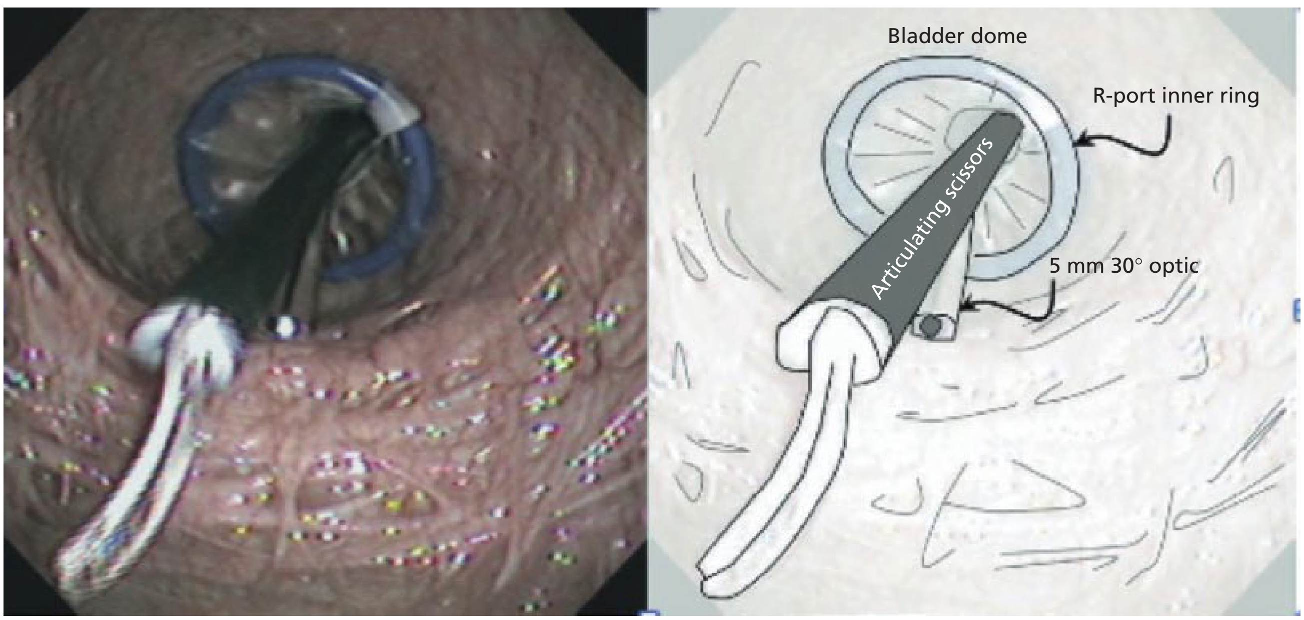

Figure135.2 Insertion and deployment of the R-port under cytoscopic guidance.

Patient position and endoscopic evaluation

All procedures are performed under general anesthesia with the patient in a modified low-lithotomy position. Initially, cystoscopy is performed and the prostate evaluated endoscopically. The bladder is filled with normal saline solution.

Insertion and deployment of the Triport

An approximately 2.5-cm skin incision is carried down to the rectus fascia. The incision is located just above the pubis. The bladder wall is identified and cleared of any prevesical fat. Two stay sutures of 2-0 Vicryl are placed.

The bladder wall is entered sharply between the stay sutures, and the inner ring of the Triport is inserted into the bladder, being deployed with the help of an introducer. The inner and outer rings are approximated by removing the slack on the plastic sleeve, thus cinching the abdominal and bladder walls between the rings of the Triport in an airtight seal. The valve of the Triport is inserted and the bladder insufflated with CO_2 to create the pneumovesicum. The insertion and deployment of the R-port is monitored cystoscopically (Figure 135.2).

The use of absorbable material for stitches in the bladder is important. These pass through its entire thickness, one in front of the other. The stitches serve as the anchor for traction and also facilitate the introduction of the trocar. They are also tied together to close the defect upon completion of the surgery.

Care must be taken that the incision in the fascia and the bladder is no more than 2.5 cm. This is because oth-

erwise the inner ring of the Triport will be dislodged. In Figure 135.2, the inner ring of the Triport is seen outside of the bladder.

Mucosal incision and enucleation

A large, bulging median lobe can be retracted anteriorly in an efficacious manner with a figure-of-eight stay stitch. This can be placed with a Keith needle or Carter–Thomason port closure needle device. The two ends of the stay stitch are retrieved and anchored outside of the anterior abdominal wall.

A Monocryl suture on a CT-1 needle is placed through the adenoma for retraction purposes (Figure 135.3A).

A U-shaped incision is made over the bladder mucosa, immediately overlying the adenoma, from the 3 o'clock to the 9 o'clock position, and through the 6 o'clock position. Typically, a reddish zone of mucosa is seen immediately lateral to the internal meatus. This serves as a reliable guide for creating the mucosal incision. The horizontal limb of the U-incision is made using a hook electrode and cutting current to reach the adenoma. The whitish prostatic adenoma is readily identified. The plane between the surgical capsule and the adenoma is created using a hook and suction cannula. The two limbs of the U-incision are created, followed by completion of the circumferential mucosal incision (Figure 135.3B).

Separate excisions of each mobilized lobe of the adenoma provide superior visualization of the remaining part of the adenoma, enabling better hemostasis.

Several maneuvers are used to facilitate the enucleation of the adenoma:

• The valve is removed first and then the right index finger is inserted through the Triport. This expedites the distal part of the enucleation. The left index finger is placed into the rectum to elevate the prostate. Once the finger dissection has been completed, the Triport valve

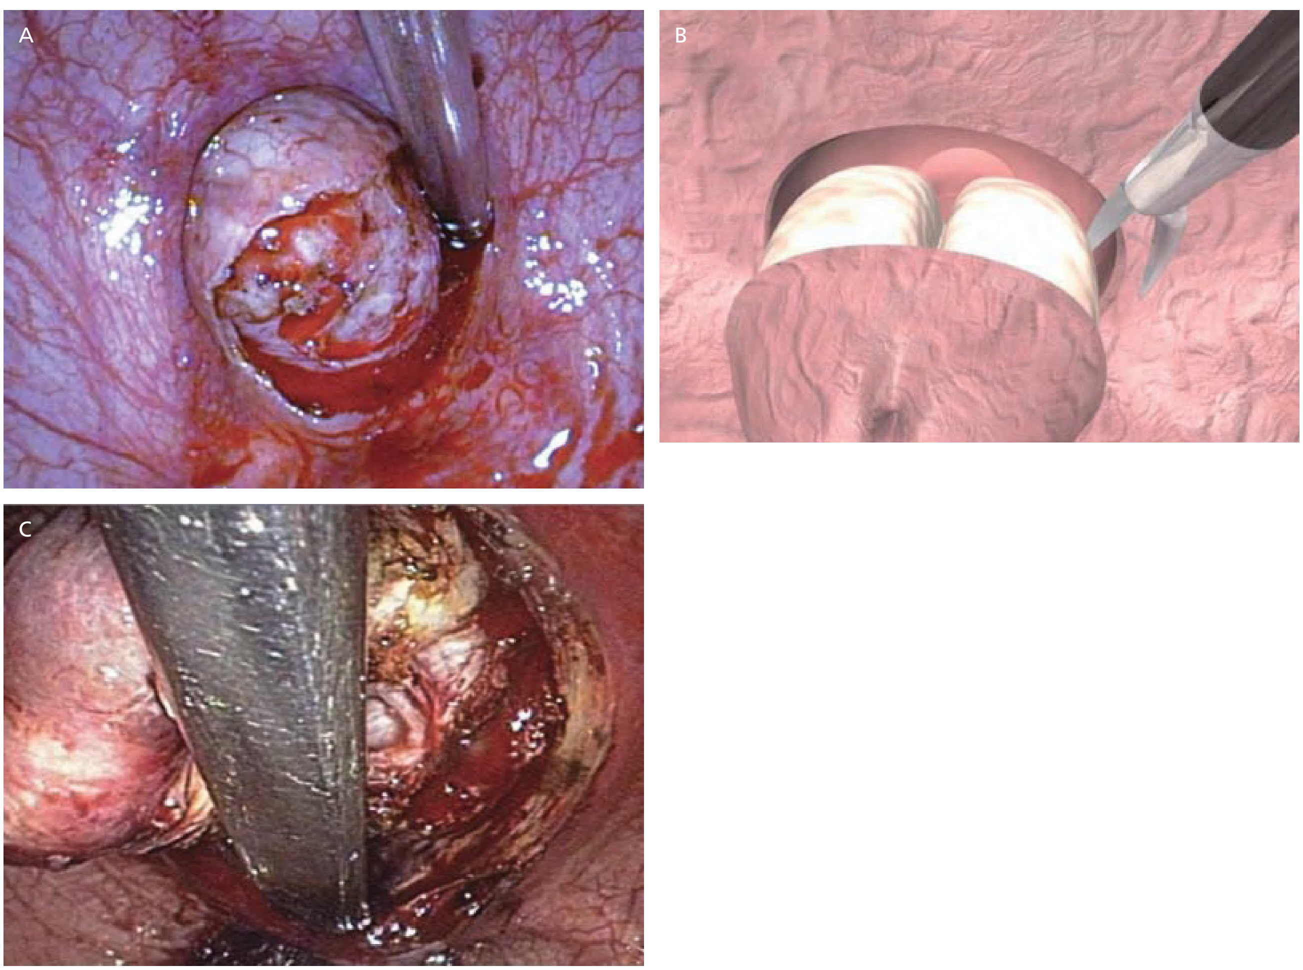

Figure 135.3 (A) A Monocryl suture on a CT-1 needle is placed through the adenoma for retraction. (B) Mucosal incision and enucleation. (C) Division of prostatic adhesions.

is reattached. The pneumovesicum is re-established for incising the urethra at the prostatic apex and completing the procedure.

• Use of the "Sotelo prostatotomy," a device similar to a curette or an osteotome, facilitates enucleation of the adenoma during laparoscopic simple prostatectomy. Its metallic, curvilinear tip, with a sharp cold knife on the distal side of the forceps, is used to divide the adhesions between the adenoma and its capsule during circumferential dissection of the gland (Figure 135.3C).

• The urethra is incised with a bipolar resectoscope through the urethra, immediately after the placement of the port and before any dissection from above (Figure 135.4).

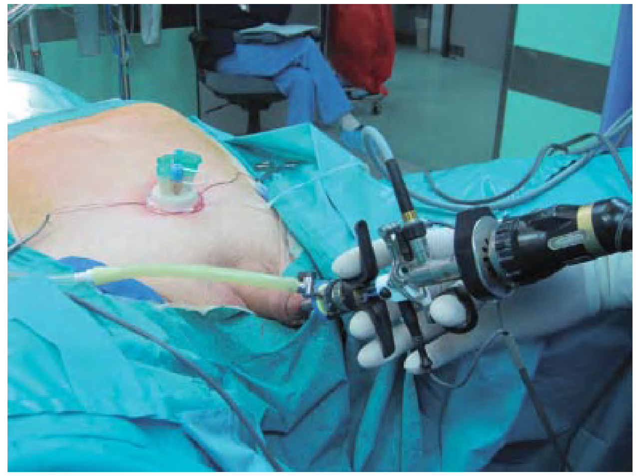

Figure 135.4 Incised of the urethra with a bipolar resectoscope.

Hemostasis

After removing the adenoma, hemostatic figure-of-eight sutures are tied down with an extracorporeal knot pusher and must be placed at the 4 and 8 o'clock positions at the prostatic capsule, to control the main prostatic vessels (Figure 135.5).

The lateral pedicles of the prostate should be thoroughly checked and the pneumovesicum pressure diminished to ensure that there is no bleeding. In the event that there is slight bleeding, it can be controlled with a monopolar or bipolar unit. If there is still any doubt, stitches can be made with absorbable sutures and knotted extracorporeally.

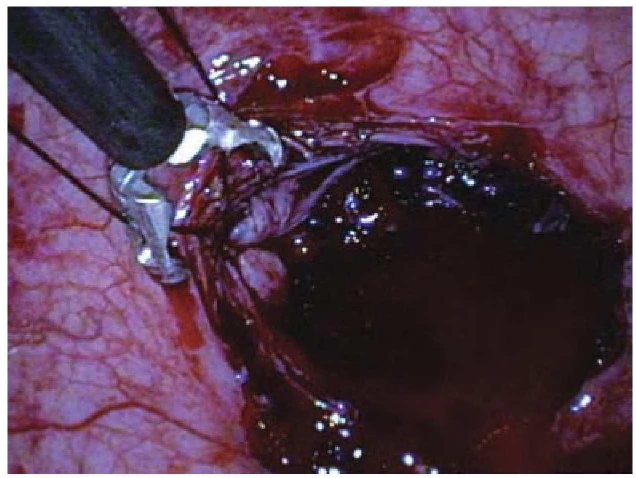

Figure 135.5 Hemostasis of the main prostatic vessels with figure-eight sutures. These are tied down with an extracorporeal knot pusher and must be placed at the 4 and 8 o'clock positions of the prostatic capsule.

Specimen extraction

The prostatic adenoma is extracted through the Triport ring after dividing it into multiple pieces during extraction with Allis forceps (Figure 135.6).

Trigonization and closure of the bladder

After adenoma removal, trigonization of the prostatic fossa can be performed by suturing the cut end of the posterior bladder neck distal toward the apex of the prostatic fossa. This can be tied down with an extracorporeal knot pusher.

The bladder opening is sutured with 3-0 Vicryl, and the fascia and skin are closed in a standard fashion.

Depending on the amount of bleeding, a suprapubic catheter can be inserted through the inner ring of the Triport (Figure 135.7). The balloon should be inflated before the Triport is removed. The ring of the Triport is large enough to pass the distal part of the catheter. In this way, it is easier to ensure that the Foley catheter is inside the bladder (Figure 135.8). Thus, the first Vicryl stay suture, which was previously placed in the bladder, can be tied, along with any additional sutures, to give a water-tight closure.

Postoperative management

Close monitoring of urine drainage is important to ensure it remains clear. It is routine to verify the postoperative hematocrit. Continuous bladder irrigation should be initiated to prevent clot formation. If significant hemorrhage is noted, the urethral catheter may be placed on traction so that the balloon can compress the bladder neck and prostatic fossa. On average, continuous irrigation is removed 12 h after verification that there is no bleeding.

On the same day as surgery, the patient can start a liquid diet. On the first postoperative day, the patient starts ambulation and a regular diet; oral analgesics can be given and parenteral narcotics are discontinued.

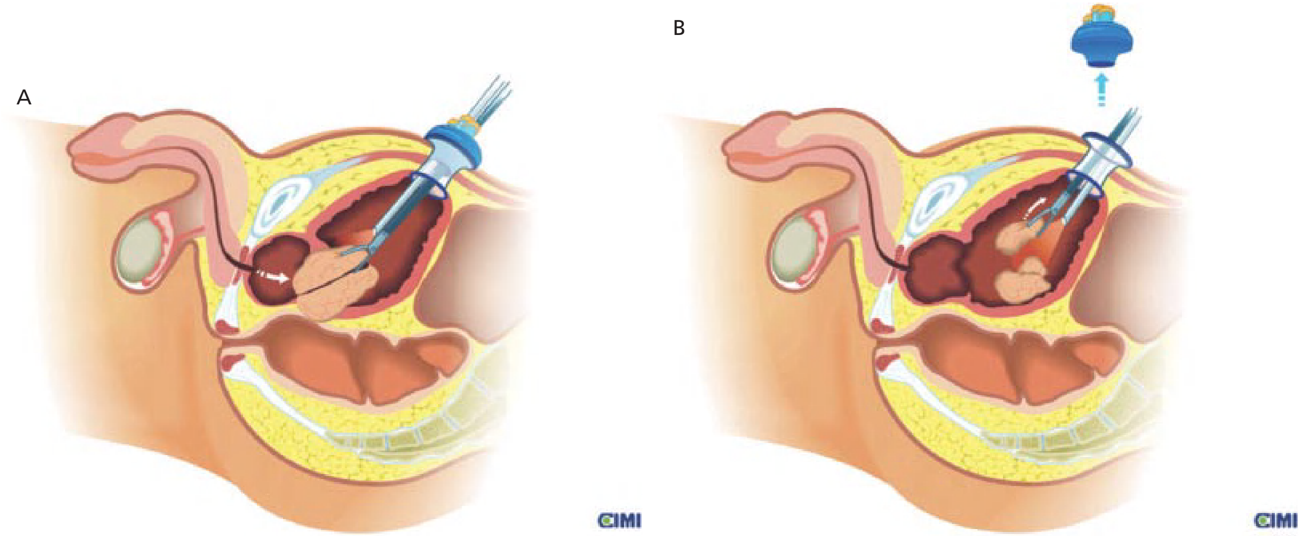

Figure 135.6 (A, B) Prostatic adenoma is extracted through the Triport ring after dividing it into multiple pieces during extraction with the Allis.

Figure 135.7 Insertion of a suprapubic catheter through the inner ring of the Triport.

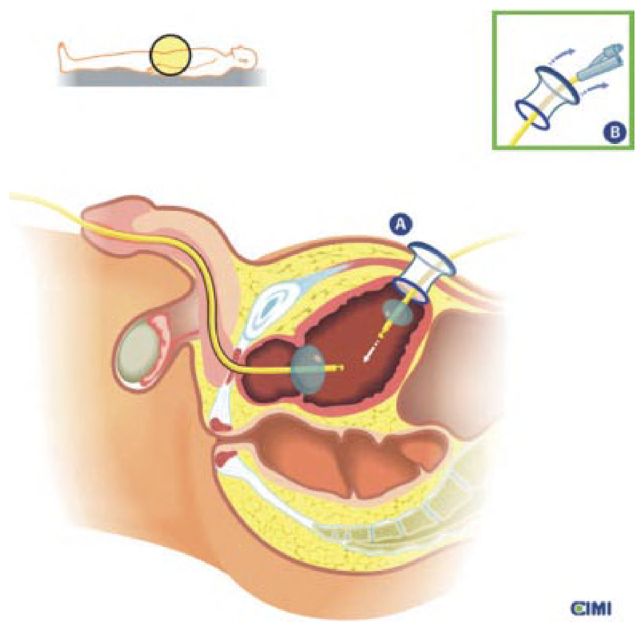

Figure 135.8 Ring of the Triport is large enough to pass the distal part of the catheter. This is the easiest way to ensure the Foley catheter is inside the bladder.

Usually the patient is discharged 24h after the procedure with appropriate discharge instructions.

The Foley catheter is removed within 5–7 days. If a cystostomy has been left, it is generally removed within 48h.

Complications

The overall rate of morbidity associated with single-port transvesical simple prostatectomy is extremely low; and to date no case of mortality has been encountered. Also, to date there have been no reports of stress incontinence, erectile dysfunction or thromboembolic events related to surgery. Stress incontinence and total incontinence are rare even for open surgery; with precise enucleation

of the prostatic adenoma, the risk of injury to the external sphincter mechanism is minimal. The incidence of urinary extravasation is practically zero with this technique because the incision through the bladder is very small, less than 2.5 cm.

The most common problem is hemorrhage, usually arising from venous structures.

Following surgery, urgency and urge incontinence may be present for several weeks, depending on the preoperative bladder status. An anticholinergic agent can help to resolve these symptoms.

Results

Our early follow-up data show that prostatic adenoma was successfully enucleated in all of 23 patients using this novel single-port transvesical technique [8]. Their mean baseline PSA was 6.6 ng/mL (1.02–23 ng/mL), IPSS 21 (11–31), and TRUS prostate size 90 mL (51–247 mL).

The mean operative time was 100 min (45–210 min) and estimated blood loss was 400 mL (50–1500 mL). Three patients (13%) were transfused. Complications were present in four patients, including the three who were transfused. One patient had an inadvertent enterotomy during port insertion that was subsequently recognized and fixed intraoperatively by open conversion after BPH enucleation had been completed laparoscopically. This patient had a history of previous exploratory laparotomy through a full midline incision for colon cancer and subsequent incisional hernia repair. A suprapubic catheter and a drainage tube were placed for safety, and the patient recovered uneventfully with a hospital stay of 3 days.

The duration of hospitalization was 2 days on average, and the Foley catheter was removed on postoperative day 7 in most of the patients. All patients were voiding spontaneously without a significant postvoid residual volume and were fully continent. The mean postoperative peak urinary flow rate after catheter removal was 41 mL/s (13–84 mL/s).

CHAPTER 136

Bladder Injections for Refractory Overactive Bladder

Mehrdad Alemozaffar & Anurag K. Das
Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Introduction

Idiopathic overactive bladder (I-OAB), as defined by the International Continence Society, is "urgency, with or without urge incontinence, usually with frequency and nocturia, [when] there is no proven infection or obvious pathology" [1]. Using this or a slightly older definition, the prevalence of I-OAB in Europe and the USA has been found to be 12.8–16.6%, with about one-third of these patients having incontinence [2–5]. Studies show I-OAB leads to deterioration in quality of life (QoL) in about 50% of patients, with the proportion increasing to 80% in those with incontinence [6]. Furthermore, these patients may experience other detrimental medical effects as a result of I-OAB, such as falls and fractures from multiple trips to the restroom, urinary tract and skin infections, sleep disturbances, and depression [7]. Additionally, patients with neurologic disorders, such as multiple sclerosis, myelomeningocele, and spinal cord injury, often experience voiding dysfunction. When this voiding dysfunction is consistent with OAB, it is termed neurogenic overactive bladder (N-OAB) [8].

The mainstay of treatment for OAB has been pelvic floor rehabilitation/behavioral therapy and anticholinergic/antimuscarinic medication, as cholinergic receptors in the bladder, stimulated by acetylcholine released from parasympathetic neurons, are responsible for bladder contraction during voiding [9, 10]. However, such receptors exist elsewhere in the body, including the brain, salivary glands, heart, gastrointestinal tract, and eyes, resulting in side effects: cognitive problems, dry mouth, tachycardia, constipation, and blurred vision. Such side effects, and a relative lack of efficacy, have led to discontinuation of anticholinergic medication in 35–45% of patients [11, 12]. Almost half of patients discontinued medication as they felt it "did not work as expected," and almost one-fourth of patients blamed the side effects [13]. Therefore, alternative methods for treatment of OAB in patients refractory to anticholinergic medications and behavioral treatments are needed and are being actively explored.

Injection of botulinum toxin A (BTX-A) into the detrusor wall of patients with refractory OAB has shown some success and is the focus of this chapter; however, alternative approaches include sacral neuromodulation and intravesical instillation of vanilloid receptor agonists such as resiniferatoxin [14, 15].

Mechanism of action

BTX is a potent neurotoxin produced by the anaerobic bacterium *Clostridium botulinum*, that can result in severe symptoms following ingestion of infected, improperly stored foods or infection of a wound. Symptoms of poisoning with BTX (mydriasis and progressive neuromuscular paralysis resulting in muscle weakness, dyspnea, and possibly death) were first described in the 1820s by the German physician Kerner, who observed an outbreak among soldiers suffering "sausage poisoning" from eating, at that time unknowningly, infected sausages [16]. It was not until 1897 that the microbiologist van Ermengem discovered the culprit bacterium that he termed "bacillus botulinus" (from the Latin word *botulus* meaning sausage) after isolating it from the tissue of several people who died following a funeral dinner as well as the smoked ham served that day [17]. The first

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

medical application of BTX was by Scott in 1977, an ophthalmologist who treated patients with strabismus or blepharospasm, and Food and Drug Administration (FDA) approval for this application was granted in 1989 [18]. Further uses of BTX approved by the FDA include cosmetic applications, treatment of excessive underarm sweating, and cervical dystonia.

Different types of BTX exist from A to F, based on specific interaction with different SNARE proteins that are required for release of acetylcholine from the presynaptic terminals, resulting in inhibition of cholinergic and neuromuscular synapses and subsequent decreased or absent muscle contractions [19].

Theories of the pathophysiology of OAB include lack of inhibition by upper motor neurons in patients with N-OAB, and over sensitivity of sensory fibers and reflex pathways in patients with I-OAB. BTX has been shown to both block these afferent fibers, resulting in a decreased sensation of fullness, and the efferent fibers responsible for the reflex bladder contractions, therefore significantly decreasing smooth muscle contractility [20–22]. BTX-A has the longest duration of action, followed by BTX-B, and these have become the focus of medical applications. Two different preparations of BTX-A exist: Botox, available in the USA, and Dysport, available in the remainder of the world. Formulations of BTX-B include Myobloc in the USA and Neurobloc in Europe.

Results for botulinum toxin a injections

Although BTX was initially thought to work only on striated muscle fibers, the efficacy of injection of BTX into the detrusor smooth muscle of the bladder wall of patients with refractory N-OAB was first demonstrated by Schurch *et al*. in 2000 [23]. In 21 patients with spinal cord injury, experiencing incontinence secondary to neurogenic detrusor overactivity, requiring clean intermittent catheterization (CIC) to empty, and having failed anticholinergics, they demonstrated a significant increase in mean maximum bladder capacity (from 296 to 480 mL, $P < .016$) and a significant decrease in mean maximum detrusor voiding pressure (from 65 to 35 cmH_2O, $P < .016$). Of the 21 patients, 17 were completely continent at 6-week follow-up and were satisfied with the procedure; improvements in urodynamic parameters and incontinence persisted at 36 weeks in 11 patients [23]. Since that initial description, many studies have demonstrated the utility of BTX injection as an appropriate second-line therapy for patients with OAB refractory to anticholinergics (Table 136.1) [24–42]. A Cochrane review also concluded that BTX-A was superior to placebo, with resulting increased capacity, decreased pressure, improved QoL, and incontinence, with higher doses being more effective [43]. Improvements in symptoms and QoL have also been described to occur to the same degree in patients with I-OAB and N-OAB, but will be described separately for simplification of comparison of different trials [44, 45].

Neurogenic overactive bladder

Two randomized, placebo-controlled trials evaluating the efficacy of BTX in patients with N-OAB have been reported (Table 136.1) [27–29]. Ehren *et al*. randomized 31 patients (17 males, 14 females) to injection of 500 U Dysport or placebo, and evaluated cystometric and QoL outcomes at 6, 12, and 26 weeks [29]. They demonstrated a statistically significant increase in bladder capacity over placebo at 6 and 12 weeks, and a decreased detrusor pressure and number of incontinent episodes throughout the trial. Additionally, patients treated with Dysport had a significant reduction in their use of tolterodine. In another trial by Schurch *et al*., 59 patients with N-OAB (36 males, 23 females) were randomized to receive Botox (300 or 200 U) or placebo, and followed at 2, 6, and 24 weeks with cystometry and QoL measures [27, 28]. Incontinent episodes were significantly decreased and QoL was improved in both treatment groups, but these parameters were unaffected in the placebo group. Cytometric measures also revealed a significant increase in bladder capacity and decrease in bladder pressures only in the treatment groups.

Further large-scale open-label trials have demonstrated the efficacy of BTX-A (either Botox or Dysport) with 68–95% improvements in incontinent episodes (Table 136.1) [30, 32]. Two studies achieved continence in about 75% of patients and were able to increase bladder capacity by 28–54% and decrease pressure by 44–52% between 1 and 3 months [31, 33].

Idiopathic overactive bladder

There have been three randomized, placebo-controlled trials of the efficacy of BTX in patients with I-OAB. Sahai *et al*. randomized 34 patients with I-OAB (15 men, 19 women) who had failed at least 6 weeks of anticholinergics to receive either 200 U of Botox or placebo and followed them at 4 and 12 weeks with cystometry and QoL measures [34, 46]. Cystometry in the Botox-treated patients revealed significant increases in maximum capacity, from 181 to 313 mL at 4 weeks and 264 mL at 12 weeks, in comparison to a decreased capacity in the placebo group from 198 mL at 4 weeks to 168 mL at 12 weeks. Patients treated with Botox had a significant reduction in urinary frequency and urge incontinence, and QoL scores improved 52%, while placebo patients did not realize any improvements in QoL measures [34, 46]. Of 16 patients in the treatment

group, six (37.5%) required CIC on a temporary basis for increased postvoid residual (PVR) volume greater than150 mL. Another study of 43 women with I-OAB by Brubaker *et al*., randomized patients in a 2:1 manner to injection with 200 U Botox or placebo [35]. The primary outcome in this trial was time to failure, defined as a response to the Patient Global Impression of Improvement (PGI-I) of no change or worse. Approximately 60% of the Botox group demonstrated clinical improvement on PGI-I with a median duration of 373 days. One month after injection, there was a significant decrease in the number of incontinent episodes in the Botox group only and QoL improved 35% compared to no improvement with placebo. CIC was needed in 43% of the Botox patients for a median of 62 days. Flynn *et al*. randomized 22 patients with I-OAB and incontinence to placebo or Botox (200 or 300 U) and followed them at 3 and 6 weeks. After 6 weeks, the Botox group experienced a decrease in urogenital distress inventory (UDI)/incontinence impact questionnaire (IIQ) of 37%, while the placebo group actually experienced an increase of 7% (i.e. they worsened); there was an increase in PVR from 25 mL to 107 mL in the Botox group [36].

Results from these initial trials were further explored in large prospective trials (Table 136.1). Following treatment with BTX, overall urinary frequency was decreased in 27–67% of patients at 1–3 months, with complete resolution of incontinence in 50–80% of patients [37–39, 47, 48]. Elderly patients (75 years of age or older, mean 81.2 years) with I-OAB have also been shown to benefit from BTX in one study, with 76.2% having a greater than 50% improvement in symptoms [49]. No urodynamic study or demographics factor has been able to predict response to BTX injection in patients with I-OAB [50, 51].

Pediatric overactive bladder

Pediatric patients with myelomeningocele experience difficulty with bladder function, and many suffer from detrusor overactivity and incontinence. Additionally, there is concern for deterioration of their upper tracts as they may have high bladder pressures due to poor or intermediate compliance and vesicoureteral reflux. Several nonrandomized studies have been carried out in children with N-OAB who are refractory to medical management (Table 136.1) [40–42]. At 3 or 4 months following injection, bladder capacity had increased by 20–162%, detrusor pressure (important for preservation of upper tract function) had decreased by 22–61%,and total continence between CICs was achieved in 73–86.7% of patients [41]. Additionally, a reduction in the grade of vesicoureteral reflux was noted in another study, potentially as a result of decreasing bladder pressure [41].

Repeat injections

As the effects of BTX injection have been shown to last approximately 6–9 months, patients require repeat injections to continue to experience the therapeutic benefits. However, initially there were many concerns raised regarding the possibility that repeat injections would result in a blunted response over time due to antibody formation to the toxin. Several studies in N-OAB patients have evaluated the efficacy of repeat injections of BTX-A, with five to seven injections over a 6–8-year period, and have demonstrated that urodynamic and clinical improvements in QoL and decreased medication requirements after the first injection were maintained for a duration of 6–9 months after each subsequent application [33, 52–56]. Results in patients with I-OAB also demonstrated the same relief after a second BTX injection; some patients who had not shown a response following the first treatment actually showed a response to the second injection [57]. Additionally, it was postulated that repeat injections could result in fibrosis from repeated puncturing of the mucosa; however, this has not been shown to occur in several studies [58–60].

Adverse outcomes

Adverse outcomes associated with the injection of BTX include urinary retention requiring CIC, urinary tract infections, and muscle paralysis. These side effects led to early discontinuation of one randomized trial after the investigators noted greater than expected residual volumes and rates of urinary tract infections [35]. Generally, an increase in PVR can be expected following BTX injection; however, the threshold for initiation of CIC differs among the various studies, ranging from 100 to 200 mL [61]. The need to perform CIC may not be an issue for a patient with N-OAB who has likely had to perform CIC in the past; however, the need for *de novo* CIC may prove very bothersome in a patient who has never had to do so. Rates of CIC following BTX vary from 8% to 43%, and CIC usually needs to be performed for about 1–3 months until PVR decreases as the effects of the BTX wear off; of note, rates of CIC are significantly increased following repeat injections in patients who experienced retention with a prior injection [47, 62, 63]. Factors that have been shown to predict a need for *de novo* CIC are a projected isovolumetric detrusor pressure of less than 50 in women (sensitivity 0.83, specificity 0.7) and a bladder contractility index of less than 120 in men (sensitivity 0.7, specificity 0.79) [62]. Peripheral muscle weakness has also been noted to occur in rare instances, and has been associated with patients receiving a higher dose (1000 U) of Dysport [30, 33].

Technical considerations

BTX injection into the bladder wall was originally described by Schurch *et al.* using a rigid cystoscope and an endoscopic needle to inject 1 mL just beneath the detrusor mucosa at 20–30 sites sparing the trigone [23]. Later the "Dasgupta technique" was described using a flexible cystoscope; a sheath is passed through the working channel of the cystoscope to protect the scope during passage of a 27G needle and to stabilize the needle during injection [64]. Additionally, a minimally invasive sedation-free technique can be performed by instillation of 40 mL of 1% lidocaine into the bladder via a catheter 10 min prior to cystoscopy [65, 66]. Therefore, BTX injection can be performed in the operating room or office with either a rigid or flexible cystoscope, depending on surgeon preference. For treatment of patients with refractory OAB, we use a modified "Dasgupta" technique to inject the detrusor submucosa at 20 sites, sparing the trigone, with 200 U of Botox diluted to 20 mL at 1 mL/site (Figure 136.1). We do not use any systemic anesthesia but place a mixture of local anesthetics in the bladder 20 min prior to the intradetrusor injections.

A

B

Figure 136.1 (A) Injection sites for botulinum toxin: 200 U of Botox diluted to 20 mL and injected into the detrusor submucosa at 20 sites with 1 mL/site, sparing the trigone. (B) Equipment used for modified "Dasgupta" technique of botulinum toxin: flexible cystoscope, sheath, and 27G injection needle.

Many of the initial studies advocated avoiding injection of the trigone as urologists felt it could lead to vesicoureteral reflux; however, this has not been shown to occur in two prospective studies [67, 68]. Injection of the trigone is not as effective in increasing capacity, but did have a greater effect on reducing urgency sensation in I-OAB [69]. Some studies have also explored injection of the urethra in patients at risk for urinary retention or with detrusor sphincter dyssynergia, with some positive preliminary results [70, 71].

The optimal dose of Botox or Dysport has not been determined. While higher doses of either drug are associated with improved urodynamic parameters, they are also associated with higher rates of urinary retention. Doses of Botox of 100, 150, 200, and 300 U have been diluted in 10–30 mL of preservative-free saline, yielding 10 U/mL, with 0.5–1 mL injected at 10–30 sites, and compared in various randomized controlled trials [28, 72, 73]. Dysport has been studied at doses of 500, 750, or 1000 U: 500 U resulted in too short a duration of action, while side effects with 1000 U were too great (there have been reports of temporary generalized weakness); therefore, many investigators have settled on using 750 U [30, 74].

Botox and Dysport have been compared head to head in only one open-label study with no obvious conclusion about which is the superior formulation [75].

Although the major focus of this chapter and of most trials has been BTX-A, BTX-B has also been investigated for use in OAB and found to have some efficacy but with a duration of only 6 weeks in limited trials [76].

The total cost of management of OAB and its consequences in the USA in 2000 has been estimated at over $US12 billion, with pharmaceutical costs constituting 10% of total costs [77]. Currently, the FDA has not approved the use of intradetrusor injection of BTX for the treatment of OAB, and thus most insurance companies do not cover such use. Therefore, most patients, unless they are involved in a clinical trial, have to pay for treatment themselves. Costs of treatment averaged £826 in the UK in 2008 (US$1 271.38) and BTX injection for treatment of OAB was determined to be cost-effective in two different analyses [78, 79].

Conclusions

A moderate percentage of patients with OAB, either from idiopathic or neurogenic causes, are refractory to anticholinergic medications and behavioral modalities, which are the first-line treatment. While patients with I-OAB may be treated with modalities such as sacral nerve stimulation (approved in the USA for this purpose), patients with N-OAB have limited alternatives, such as bladder augmentation. Endoscopic injection of BTX-A into the detrusor wall is gaining acceptance

as a second-line therapy in these patients as studies have demonstrated clinical and urodynamic efficacy, resulting in fewer incontinent episodes, improved QoL, and increases in bladder capacity and decreases in maximum detrusor pressures. These beneficial results last approximately 6–9 months and injections can be repeated as necessary with no apparent tachyphylaxis. However, patients can experience increased residual volumes requiring CIC for 1–3 months until spontaneous voiding can resume, and also are at a higher risk for urinary tract infections. In general, doses of 100–200 U of Botox or 500 U of Dysport are injected for patients with I-OAB; 200–300 U of Botox and 750 U of Dysport for patients with N-OAB; and 10 U/kg (up to a maximum of 300 U) for the pediatric population. While surgeon preference determines whether injection of Botox is carried out with a rigid cystoscope under systemic sedation, many experienced investigators are using a flexible cystoscope and intravesical anesthesia in the office setting. Whether the use of Botox will become common in I-OAB remains unclear, but the primary deterrent would be the unpredictable need for CIC in this population. While Botox in the neurogenic population is effective and many of these patients already perform CIC, in a young patient who may require injections of Botox every 9–12 months, the advantages and disadvantages of reconstructive surgery (augmentation cystoplasty) need to be carefully considered.

CHAPTER 137
STING Procedure for Reflux

Steve J. Hodges
(Pediatric Urology) Institute for Regenerative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, USA

Introduction

The endoscopic treatment of vesicoureteral reflux (VUR) involves the injection of a bulking agent at the orifice of an incompetent ureter in order to create a suitable flap–valve mechanism to prevent the retrograde flow of urine during voiding. Many different types of bulking agents have been used in the history of endoscopic reflux therapy, although the perfect agent has been elusive. The ideal substance for endoscopic treatment of reflux should be easily injectable, nonimmunogenic, stable, and safe for human use [1].

Search for the ideal bulking agent

Matouschek was the first to describe the endoscopic treatment of VUR in 1981 when he detailed the injection of Teflon® polytetrafluoroethylene (PTFE) at the ureteral orifice to increase resistance to urine back flow [2]. Following the publication of excellent results using the subureteral PTFE (Teflon) injection (the STING technique) by O'Donnell and Pruri, the procedure received general acceptance in Europe, but was not widely used in the USA, where there was concern over implant migration [3]. The numerous reports of PTFE migration to remote areas such as the brain and lung following injection in the urethra and bladder neck sealed the fate of PTFE therapy [4, 5]. In addition to the risk of migration, there was concern over the development of granulomatous reaction around the PTFE, leading to possible calcification and making subsequent reimplant surgery difficult [6].

Once it was clear the future of the endoscopic treatment of reflux would not include PTFE, scientists searched for other agents to be used in the desirable technique. Silicone (Macroplastique; Urpoplasty Inc, Minneapolis, MN, USA) was a very effective agent when used with the STING procedure, correcting reflux in over 80% of ureters, with little morbidity. Unfortunately, silicone can cause a local foreign body reaction, and on the basis of the variable size of its particulates (35–540 μm), has a theoretical potential for migration risk. Also, the difficulty in injecting the viscous solution made the procedure less desirable. Finally, Macroplastique came to light at a time of great concern over systemic collagen disorders arising from silicone implants, and the material never achieved popular use [1, 7].

The next agent to be explored for the endoscopic therapy of reflux was glutaraldehyde-cross-linked bovine collagen (Contigen; C. R. Bard Inc, Murray Hill, NJ, USA). This substance has several characteristics that limited its widespread use for the STING procedure. First, it has the possibility of an allergic reaction, and therefore demands requisite allergy testing preinjection. Also, as has been noted in other areas of collagen injection (in cosmetic surgery, or the urethra for intrinsic sphincter incontinence), the substance has a limited staying power, and can show significant volume loss over time from the site of injection. Finally, long-term efficacy was not comparable to other, more durable agents [1, 7].

Calcium hydroxylapatite (Coaptite; Boston Scientific Inc, Natick, MA, USA) is a mixture of water and glycerin with 3% methylcellulose gel. It had commendable

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

results in studies on patients with reflux requiring endoscopic correction, but had a higher single injection failure rate when compared to competing agents. The material is thought to be biocompatible and nonmutagenic, and currently is indicated only for female stress urinary incontinence secondary to intrinsic sphincter deficiency [1].

As research into tissue engineering expanded in the 1990s, one of the first areas investigated for human use involved the growth of chondrocytes for the treatment of VUR in children. Autologous chondrocytes were harvested from the auricular cartilage of patients and 6 weeks after their harvest and growth in culture, they were suspended in an alginate solution that included calcium chloride and calcium sulfate, which provided a scaffold for cartilage formation. The cells were then injected cystoscopically using the STING technique. The elastic cartilage tissue formed was able to correct VUR without any evidence of obstruction, and represented the first human application of cell-based tissue engineering technology for urologic applications [8].

However, the costs of the technique, as well as the need for a second harvesting procedure, limited the widespread use of the technology. In addition, variable degrees of cell growth appeared to occur, leading to inconsistent success rates [9].

Another novel material for use in the STING procedure was introduced in the late 1990s. Cross-linked dextranomer and hyaluronic acid (Deflux) had been used safely in the body for other indications for years, with no migration and long-term durability. Deflux has many of the characteristics of an ideal and effective bulking agent, as it is thin enough to allow needle injection, yet viscous enough to maintain its volume, is biocompatible, elicits minimal inflammation, and maintains its periureteral configuration over time [10].

Since the introduction of Deflux and its acceptance into widespread use, it has demonstrated excellent results and durability, and has become the agent of choice. As experience has grown with the use of Deflux, the techniques, methods, and circumstances of use have all evolved.

Technique

The traditional STING procedure involved the injection of bulking material just outside the ureteral orifice at the 6 o'clock position, elevating a mound with the compressed ureteral orifice located at the top of the hillock. Using the traditional STING technique, the success rates with Deflux injection, while variable, were acceptable, but certainly lagged behind those of surgical reimplantation. The Atlanta group pioneered a novel method, termed "HIT" and now "double HIT,", which has raised the success levels of Deflux injection above 90% [11, 12].

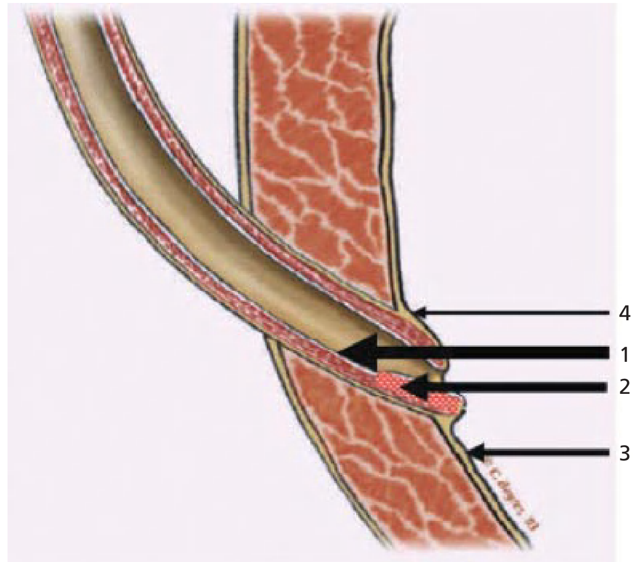

Figure 137.1 Locations of needle placement for the 1, intraureteric proximal technique (HIT); 2, intraureteric distal technique (double HIT); 3, traditional STING technique; and 4, superior tunnel (reproduced from Molitierno *et al.* [13], with permission).

In this method, the ureter is hydrodistended so that the needle may be placed inside the ureteral tunnel, a few millimeters within the orifice (see Video 137.1). This allows the first injection of the HIT technique to track bulking agent along the ureteral sheath, and more efficiently coapt the ureter (especially larger, dilated ureters). The second hit is similar to the traditional STING injection, but is slightly more cephalad, and coapts the ureteral orifice and elevates a mound of bulking material at the terminal ureter (see Video 134.2 for the complete double-HIT technique). This technique creates a "mountain range" of bulking material along the course of the ureter, as opposed to the original simple hillock (Figures 137.1 and 137.2) [13].

The double-HIT method has not only been employed for primary VUR (90% cure), but also for repeat endoscopic injections (90%), VUR associated with paraureteral diverticula (81%), complex cases such as post reimplantation (88%), neurogenic bladders (78%), duplication anomalies (80%), and in adults (88%). Several other studies have supported the use of Deflux in the setting of anatomic variants such as duplex systems as well [13–16].

The experience with the double-HIT technique was also important in identifying the need for sometimes large volumes of injectable material for cure. There is considered to be a 20% volume loss over time when using Deflux, so as a matter of technique it is important to use an adequate amount of material so that cure is ensured. Limiting the amount injected in an effort to

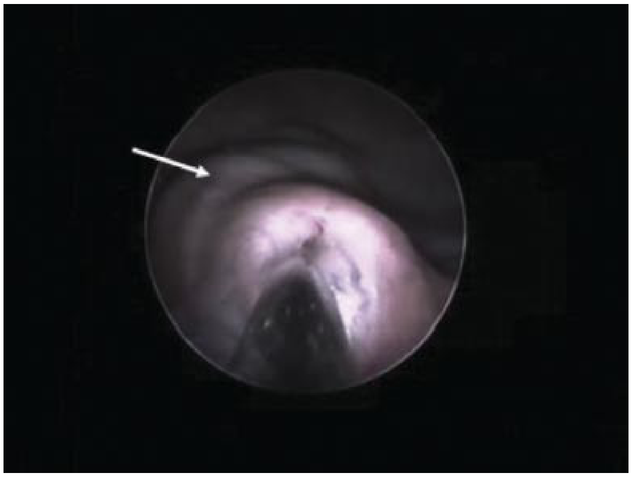

Figure 137.2 "Mountain range" mound (arrow) produced by the double-HIT injection technique (reproduced from Molitierno *et al.* [13], with permission).

limit costs often results in increased expenses later as failure rates are higher [17]. Also, failure is usually due to caudal migration of the bleb, so more proximal injection using the double-HIT method, as well as the larger volumes, has improved results [13].

The use of hydrodistention in these procedures also led to studies correlating the degree of ureteral distention with reflux. A grading system has been developed for ureteral dilation, which correlates well with grade of reflux. The hydrodistention grading system defines grades of reflux as: H0, no hydrodistention; H1, ureteral orifice open but tunnel not evident; H2, tunnel seen only, and H3, extravesical ureter visualized (Figure 137.3). In studies, VUR and dynamic hydrodistention classification grades correlate significantly ($P < .001$), and provide a reliable method of evaluating the presence or absence of VUR. These findings, combined with the studies demonstrating a lack of correlation of intraoperative cystogram and late cure, have allowed surgeons to do away with the postoperative cystogram (at the time of the injection), as lack of hydrodistention can confirm cure [11, 18].

Follow-up

Follow-up for STING procedures varies. As mentioned, it has been determined that a cystogram is not needed at the time of injection, as ureters that do not hydrodistend are considered cured. Cystography may, however, pick up contralateral unrecognized reflux, which may then be easily treated [19].

Traditionally, patients are observed for approximately 3 months on prophylactic antibiotics and then studied with renal bladder ultrasound and voiding cystourethrogram (VCUG) following injection therapy. In cases where the expected cure rate is high, the VCUG may be avoided and children do well. There has been some research into the appearance of injected bleb on postoperative ultrasound and cure rate. One study has demonstrated that while there is no difference in the volume of the visible Deflux on postoperative ultrasound in cures and failures, when a greater than expected volume of Deflux is retained (termed mega-implant), the cure rate is much higher than in cases with a less than expected volume remaining (micro-implants) or no visible implant [17]. The same study demonstrated durable implant size over 36 months postoperatively in these patients [17].

The bleb at the site of Deflux injection can persist long term, and this raises issues for future imaging and misinterpretations of the mass. Studies have demonstrated that the blebs can appear as calcifications on computed tomography (CT) scans and be mistaken for ureteral stones, and appear bright on T2-weighted images, but do not enhance on T1 scans [20–22]. It is important to note the history of intervention in these patients, so unnecessary medical interventions are not performed for these findings. The pathologic description of Deflux material has also been well described, so any tissue sent for pathologic evaluation in cases of reimplantation after injection therapy should be readily identifiable [23].

Long-term data regarding Deflux (approved for use in 2001) are not readily available, but some small studies have demonstrated durable results. Published results on the long-term efficacy of endoscopic use of Deflux for VUR have concluded that subureteral injection of Deflux for children with VUR is an effective and durable treatment option for VUR with a low complication rate. Other studies, however, have raised great concerns for the long-term efficacy of Deflux, as there may be a high documented rate of late recurrence. However, these patients with later failures had risk factors, such as dysfunctional elimination, which may have contributed to the poor results. For now it seems prudent to follow these children closely for several years until durable and reliable long-term data are available [24–26].

Role of the STING procedure

Typical of many areas in pediatric urology, the treatment of VUR is highly controversial. The opinions on STING therapy for reflux vary from religious opposition to overzealous support. The exact role for Deflux therapy remains to be defined, but it is clear that it is gaining a more prominent position in the armamentarium of the surgeon treating various forms of reflux. Studies have expanded its role from simple refluxing ureters, to more complex systems, such as duplicated ureters, ureters

Hydrodistention Grade	Description	Cystoscopic appearance	Example
H0	No orifice distention evident		
H1	Orifice opens Intramural tunnel not evident		
H2	Orifice opens Intramural tunnel evident Extramural ureter not evident		H3	Orifice opens Extramural ureter evident or ureter can accept cystoscope		

Figure 137.3 Hydrodistention grading system developed by Kirsch *et al.* (reproduced from Kirsch *et al.* [18], with permission).

associated with diverticula, transplant ureters, and even ureters in neurogenic bladders. The appeal of STING therapy to many is that the procedure poses minimal morbidity with the chance of great reward if a cure results. If cure is not achieved, the grade of reflux is often downgraded to a less clinically significant level, and repeat injections may also be preformed. Once STING has failed twice, all experts agree that any surgical intervention needed should then proceed to open reimplantation, and surgery following even repeat Deflux procedures is only slightly more difficult than virgin surgery. In summary, this procedure may offer a simple cure, while not burning any bridges [27].

There is a concern that Deflux injection, being a relatively simple procedure, will be overutilized to the detriment of patients. As with any technology or procedure, the clinician's judgment is crucial to the success of the methodology chosen, and judicious use of any technique is a must [28].

As with any new technology, some have attempted to push the envelope with mixed results. Some have used Deflux in combination with botulinum toxin A injection

as a means of total endoscopic management of a noncompliant neurogenic bladder. These combined therapies were able to decrease bladder pressure and the rate of urinary tract infections (UTIs) [29].

The detractors of STING therapy point to studies expressing low cure rates per ureter, extolling that it is in the best interests of the patient to provide a one time, highly successful surgery. The proponents rely on the support of studies stating higher cure rates, and the "less is more" philosophy of surgical intervention. It seems that these differences are often philosophical, and depend on the personality, experiences, and training of the surgeon, and all the studies published have done little to sway adherents from either camp to the other side.

A unique benefit of the STING procedure is that it can easily be paired with a positionally instilled cystogram (PIC) as a simple procedure to diagnose and treat VUR. Studies have demonstrated that children with recurrent febrile UTIs with negative VCUG studies may have occult reflux (as VCUGs have a known false-negative rate), and these cases can be diagnosed and treated with PICs followed by Deflux injections. The PIC is performed by using cystoscopy with contrast running as the irrigation fluid and pointing the beak of the cystoscope at the ureteral orifice in a partially filled bladder. Fluoroscopic images of reflux are considered proof positive of occult reflux, and treatment with STING therapy is almost always the next option. Considering the relation of ureteral hydrodistention and reflux grade, it may be debatable as to whether contrast instillation is necessary in an obviously distended system (grade 3), but documentation of the pathology is always helpful in justifying the therapy [30, 31].

Another interesting area of research into the uses of the STING procedure for reflux therapy has been the push by proponents of the technique to use it as a first-line therapy for reflux. These authors point to the low patient compliance with prophylactic antibiotics, claiming that first-line injection therapy would be a more inexpensive, simpler option for families, with little morbidity. For example, Hensle *et al.* noted that only 17% of patients with VUR on prophylaxis are compliant and that 58% had a diagnosis of UTI within 1 year of treatment [32]. Elder *et al*. demonstrated that treatment with Deflux in children with reflux resulted in fewer UTIs than management with prophylactic antibiotics, and concluded that Deflux should be considered first-line therapy [33]. Koyle and Caldamone made a case that misuse of antibiotics has spread resistance, and thus should be replaced by first-line Deflux therapy in appropriate patients [34].

There is a general lack of controlled studies regarding prophylaxis, although efforts are underway to ameliorate this deficiency. The RIVUR study (Randomized Intervention in Children with Vesicoureteral Reflux) is designed to determine whether small doses of antibiotics can prevent recurrent UTIs and/or kidney damage, although recruitment has been slow. In general, compliance is low with antibiotic prophylaxis, but that does not mean that the therapy is ineffective or not worthwhile. When given appropriately, prophylaxis does prevent infections, and does not have a large impact on microbial resistance [35]. All parents should have all options discussed with them on visits with their child's pediatric urologists (from open surgery to prophylaxis), and prophylaxis remains standard first-line therapy. New innovations, including injection therapy, should be closely studied and offered in an unbiased fashion.

With the availability of minimally invasive techniques, such as extravesical ureteral reimplantation, mini-ureteroneocystostomy, and extravesical and intravesical laparoscopic and robot-assisted procedures, there has been a push by some surgeons to prove that traditional ureteral reimplantation can be performed with new techniques and technology in an outpatient setting, with comparable morbidity and higher cure rates than with endoscopic procedures. Some studies have also demonstrated decreased total cost with these procedures. It is clear that as minimally invasive surgical technology advances, there will be pressure on the endoscopic options of therapy to maintain high cure rates to compete with these increasingly inexpensive and benign procedures [36–38].

The choice of therapy for VUR remains controversial. The main goal of preventing renal scars and infection in these young children must be kept in mind, and we are fortunate to have a multitude of excellent options to choose from to achieve this goal. In the hands of a trained pediatric urologist, with close follow-up of their patients, all three options of antibiotic prophylaxis, STING therapy, and open surgery can be used wisely in an effort to maintain urologic health.

Dysfunctional elimination

It is our opinion that as the identification and treatment of dysfunctional elimination improves, the rates of resolution of refluxing ureters will also improve (as well as the success rates of STING procedures), obviating the need for open surgery in most children [39]. In fact, the Atlanta group currently reserves open surgery only for patients who fail injection therapy (two injections), have high-grade reflux or megaureters (that require tapering), and if this is the preference of the parents [13].

Results have been published showing that the treatment of dysfunctional elimination does not affect the success of endoscopic therapy of reflux, but the definition of dysfunctional voiding and the documentation of its successful treatment are not always well documented

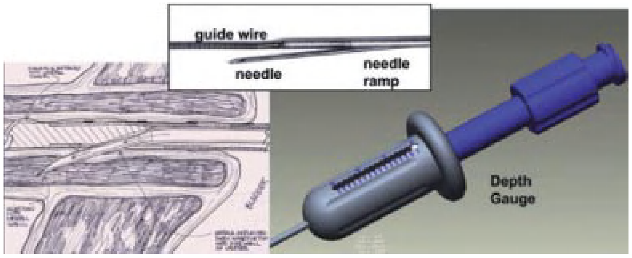

Figure 137.4 Cook Injekt VUR Injection needle. The device has a filiform tip with markings to help physicians achieve proper needle position and depth relative to the ureteral orifice for precise placement of the bulking agent (reproduced from Molitierno *et al.* [13], with permission).

or proven [13, 40]. Our center has unpublished data showing that the incidence and severity of dysfunctional elimination is widely underestimated, and that a focus on biofeedback and constipation therapy may greatly reduce the incidence and severity of reflux in children.

Conclusions

The introduction of Deflux into the realm of endoscopic reflux therapy has provided surgeons with an almost ideal bulking agent, and allowed for the expansion of the STING procedure. The techniques have improved, as well as the results, and endoscopic therapy has become a reasonable option for almost all children with reflux, and in some circumstances a good first option. As the treatment of dysfunctional elimination becomes more codified and widespread, the need for open surgery will likely wane, while the numbers of endoscopic cases will continue to expand. The growing experience among practicing urologists, standardization of techniques, and introduction of new tools that help the consistency and accuracy of needle placement (Figure 137.4) will help ensure reproducibly high success rates for endoscopic therapy in the future.

CHAPTER 138

Minimally Invasive Therapy for Interstitial Cystitis/Painful Bladder Syndrome

Sylvia Montag & Robert Moldwin

The Smith Institute for Urology, Hofstra North Shore–LIJ School of Medicine at Hofstra University, New Hyde Park, New York, USA

Introduction

Interstitial cystitis (IC), also known as painful bladder syndrome (PBS), is a common disorder of the urinary bladder affecting mostly young and middle-aged women; however, it has also been reported in men in whom it is often difficult to distinguish from chronic prostatitis. This clinical syndrome is a diagnosis of exclusion and no single treatment has yet been established to alleviate all symptoms. Increasing evidence links comorbid conditions to IC/PBS, allowing for investigation of potential pathologic pathways and application of novel therapies. This chapter will review IC/PBS with focus on minimally invasive treatment options.

Definition/nomenclature

IC/PBS is a disorder primarily manifest by bladder/pelvic pain and irritative voiding symptoms, such as urgency and/or frequency. Once considered a disease process related only to the bladder, it is becoming increasingly evident that the condition may associate with other pain syndromes and medical conditions affecting multiple organ systems [1]. The constellation of IC/PBS symptoms has been assigned different names to reflect its broad clinical spectrum, and this continues to evolve. The International Continence Society (ICS) prefers the term painful bladder syndrome (PBS), while the European Society for the Study of Interstitial Cystitis proposed the name "bladder pain syndrome."

Two different forms of IC/PBS have been described, and prognosis and treatment may vary depending upon the form detected. "Classical" disease is characterized by erythematous patches, termed Hunner's ulcers (or Hunner's patches), after Guy Hunner, the surgeon who first described these lesions. Hunner's ulcers occur in less than 10% of patients [2, 3]. Only cystoscopy can accurately determine if inflammatory disease is present, as only approximately 30% of these patients show abnormalities on urinalysis that would otherwise prompt a cystoscopic examination. "Nonclassical" disease is characterized by a normal cystoscopic examination in the face of typical symptoms and no evidence of any other pathology [4].

Epidemiology

Considering the difficulty of establishing an accepted definition, collected data have been difficult to interpret and this has led to variations in reported prevalence around the world. In a large study from Finland, the estimated prevalence in women was 230 per 100 000, and a study of urban females in Vienna, Austria gave an overall estimate of 306 per 100 000 women, with the highest prevalence (464 per 100 000) among middle-aged females (40–59 years old) [5, 6]. Similarly, a US population-based study found the prevalence to be 197 per 100 000 women and 41 per 100 000 men [7]. Screening and data collection based on symptoms rather than diagnosis show the prevalence to be much higher. A primary care office survey screening patients for symptoms of IC

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

estimated the prevalence to be 12 600 per 100 00 women [8]. Studies by Parsons *et al*. suggest that IC is highly prevalent in young women and may affect as many as one in four [9, 10]. The female-to-male ratio is reported as approximately 10 : 1 [7, 11]. However, given the difficulty in distinguishing between IC/PBS and the chronic pelvic pain syndrome (CPPS) that affects men, the percentage of males with IC/PBS may be underestimated and the ratio is likely closer to 5 : 1 [12, 13].

Most patients with IC/PBS are adults, but the condition has been reported in children and young adults [14, 15]. The presence of childhood bladder problems, such as dysfunctional voiding or enuresis, is reported to be 10 times higher in IC/PBS patients versus the general population.

Data further suggest that IC/PBS has a negative effect on quality of life. IC/PBS often coexists with conditions such as depression, chronic pain, anxiety, and poor overall mental health [11].

Etiology

While a single cause of IC/PBS remains unknown, numerous pathologies have been documented. Increasing data suggest that IC/PBS may be a systemic disorder with bladder symptoms and pelvic pain being the main manifestation [16, 17]. Some evidence exists of a genetic predisposition to IC/PBS. Adult female first-degree relatives of patients with IC/PBS are reported to have a prevalence of IC/PBS 17 times that found in the general population [18]. Additionally, there is a greater concordance of IC/PBS among monozygotic than dizygotic twin pairs, strengthening the evidence for genetic susceptibility to IC/PBS [19].

An infectious etiology for IC/PBS has been proposed. Various pathogens, including bacteria, viruses and fungal agents, have been investigated, but even highly sensitive and specific molecular methods for identifying infectious agents by detection of DNA or RNA were unable to demonstrate any particular microorganism or virus responsible for the development of IC/PBS [20]. Another infection-related theory is that pathogens subvert host defense mechanisms, leading to frequent clinical or subclinical infections. This, in turn, may lead to the activation of neuroimmune pathways and the development of IC/PBS symptoms [21]. At this time no conclusive data exist to support an infectious etiology and it is unlikely that an active infection is involved.

Several other nonmutually exclusive theories that may help explain the pathogenesis of IC/PBS have been described in detail and are summarized in Table 138.1. Briefly, immune/neuroimmune mechanisms may have an important role in the pathogenesis, including excessive release of neurotransmitters, mast cell-mediated inflammation and morphologic changes in the nerves innervating the bladder. Several investigators have tried to establish the link between IC/PBS and autoimmune pathways; however, the pathways are not well defined and it is possible that the autoimmune phenomena described in IC/PBS patients are coincident [11].

Following the recognition of mast cells within the bladder wall, numerous studies were aimed at elucidating any possible role for them in the pathogenesis of IC/PBS. Mast cells play a primary role in allergic disorders and acute inflammatory response. These cells are also implicated in angiogenesis, wound healing, bone remodeling, arthrosclerosis, and reaction to neoplasms. Multiple components, such as endocrine, immune, and neurologic pathways, are suggested to contribute to the pathogenesis of IC/PBS and activated mast cells play a central role in the activation and signaling of these pathways, linking these cells to the disease process [22–24].

The bladder surface epithelium is lined by bladder surface mucin, a continuous layer of proteoglycans and

Table 138.1 Potential mechanisms involved in the pathogenesis of interstitial cystitis (adapted from Theoharides *et al*. [36]).

Mechanism	Pathophysiologic effect
Bladder lining abnormalities	Damage to the bladder protective glycosaminoglycan layer
Abnormalities of descending inhibitory pain pathways	Dysfunction in brain centers (or the pathways from these centers) that normally downregulate pain signaling in the spinal cord
Neurogenic inflammation	Increased bladder neuropeptide containing nerve endings juxtaposed to increased and activated mast cells, increased urine interleukin (IL)-6
Neurohormonal dysregulation	Dysfunction in the hypothalamic–pituitary–adrenal axis, including higher bladder expression of corticotropin-releasing hormone (CRH)
Decreased urothelial repair	Increased secretion of antiproliferative factor (APF) shown to inhibit urothelial cell growth *in vitro*
Comorbid conditions	Mechanism unknown; increased rate of psychiatric comorbid conditions, including depression, anxiety, post-traumatic stress, and somatization, as well as allergies, chronic fatigue syndrome, endometriosis, fibromyalgia, IBS, and IBD [13,25, 80–88]

glycosaminoglycans (GAGs). This layer (commonly called the "GAG" layer) is thought to provide both a permeability barrier to noxious solutes in the urine and a host defense against bacterial adherence. Injury or destruction of the protective layer leads to increased epithelial permeability and susceptibility to infection. The absence of this layer and its protective function can be duplicated by application of exogenous GAG. Increased mucosal permeability is nonspecific and can be a consequence of bladder inflammation, injury or chemical cystitis, and it may be part of the normal process of aging. Parsons and Hurst hypothesized the concept that IC/PBS in a subset of patients is the result of some defect in the epithelial permeability barrier of the bladder surface GAG [25]. Multiple investigators have demonstrated a link between increased mucosal permeability and GAG layer damage, but whether this represents a primary cause of IC/PBS or merely reflects a secondary event is unclear [26–28]. An argument against the "GAG theory" is that injury to this protective layer via fulguration of bladder lesions, bladder hydrodistention, or the intravesical administration of clorpactin or the organic solvent dimethyl sulfoxide (DMSO) may improve bladder symptoms. On the other hand, treatments aimed at "restoring" the GAG layer have a role in the treatment of IC/PBS and will be discussed later in the chapter.

Inflammation, especially if repeated or chronic, can alter tissue innervation, central pain processing mechanisms, and tissue response. Neuropeptides present in the spinal cord have an important role in the mediation of nociceptive input, which, under pathologic conditions such as inflammation can be altered, leading to functional consequences. Activation of pain fibers can trigger neurogenic inflammation through release of neuropeptides and subsequently increase vascular permeability. Furthermore, mast cell degranulation can be stimulated by neuropeptide mediators, leading in term to exacerbation of inflammation, injury, and increased epithelial permeability. Numerous studies also indicate increased sympathetic activity in patients with IC/PBS [29–31]. Neurogenic inflammation is compatible with the central role of mast cells and the leaky epithelium theory. Dysregulation of the pelvic floor, resulting in chronic pelvic pain, may be the result of central nervous system upregulation and augmented sensory processing. New treatment possibilities may arise from further investigation and better understanding of the neurobiology and its role in the pathogenesis of IC/PBS [11].

Investigation by Keay *et al*. into the role of certain cytotoxins in the epithelial damage seen in IC/PBS led to the discovery of the antiproliferative factor (APF) [32]. In further studies, the presence of this factor was found to be a sensitive and specific biomarker for IC/PBS. The presence of APF significantly decreases levels of heparin-binding epidermal growth factor-like growth factor (HB-EGF) and at the same time upregulates the levels of epidermal growth factor (EGF), which leads to inhibition of primary urothelial cell proliferation. Urine levels of APF, HB-EGF, and EGF reliably separate out IC/PBS patients from controls [33]. The presence of APF activity has been shown to differentiate between men with IC/PBS versus CPPS/chronic prostatitis [34]. These tests are not commercially available.

Signs/symptoms and diagnosis

IC/PBS is a clinical diagnosis of exclusion based upon chronic (3–6 month) pain or discomfort perceived to be bladder based. The pain usually varies with the degree of bladder distention; hence, urgency and frequency of urination are usually present in an attempt to minimize discomfort. Urinary tract infection and other potential treatable causes must be excluded. Median age of presentation in women is 40–45 years [35]. According to reports from the interstitial cystitis database, the most common baseline pain sites are lower abdominal pain (80%), urethral (74%), and lower back (65%). Most patients describe intermittent pain of moderate intensity and there have been reports of links between pain sites and urinary symptoms [35]. The pain often worsens with filling of the bladder and may be relieved by voiding [36]. Men compromise about 10–15% of IC patients. There is significant overlap in symptomatology when comparing IC/PBS and chronic nonbacterial prostatitis. Frequently associated findings in men are erectile dysfunction, painful ejaculation, and microhematuria. Urinary frequency is less commonly reported [12].

No reports point to IC/PBS as a potential premalignant condition; however, it is important to rule out bladder cancer, especially the presence of carcinoma *in situ* in patients aged over 40 years with a smoking history. Other rarer conditions, such as eosinophilic cystitis, malacoplakia, scleroderma, schistosomiasis, and detrusor endometriosis, must also be considered. In women, gynecologic problems, specifically endometriosis, can mimic the IC/PBS symptom complex and careful evaluation to rule out any correctable condition should be undertaken. Patients evaluated for IC/PBS may report urgency along with other symptoms and a diagnosis of overactive bladder (OAB) should be considered. Urgency felt by patients with IC/PBS is considered secondary to pain rather than the impeding loss of control typical for OAB [11]. A large-scale survey of individuals diagnosed with IC/PBS showed an unexplained association with other chronic disease and pain syndromes. Allergies, irritable bowel syndrome, and sensitive skin were the most common associated conditions [37]. Although not based on randomized trials, small observational studies suggest that high levels of stress tend

to increase pain and urgency in patients with IC/PBS [38, 39].

Patients considered for a diagnosis of IC/PBS should have a careful evaluation, starting with assessment for increased daytime and night-time frequency, and suprapubic pain/pressure/discomfort related to bladder filling. In 1987, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) developed a list of clinical criteria to better identify patients with IC and compare data collected from different geographic areas [40]. Due to the restrictive nature of the NIDDK criteria, use in clinical practice would likely miss an estimated 60% of patients and should be restricted to research only [41].

A thorough medical history should include the presence of allergies, gastrointestinal, gynecologic, autoimmune, and musculoskeletal disease. Symptoms can be evaluated using any of the validated questionnaires, all of which are designed to assess severity of symptoms rather than to serve as a diagnostic tool. Symptom scales available include the one-page O'Leary-Sant Symptom and Problem Index, the University of Wisconsin Symptom Instrument, and the Global Response Assessment (GRA). These scales can also be used to measure response to treatment and are valuable in clinical research.

A presumptive diagnosis can be made solely based upon the history and physical examination, and other testing to exclude other well-defined illnesses. Urinalysis and urine culture are part of a standard urologic evaluation for the IC/PBS patient. Further evaluations with urine cytology, special cultures (such as testing for acid-fast bacilli), office cystoscopy, urodynamics, and radiographic imaging are performed based upon the patient's clinical presentation and history.

Hydrodistention under anesthesia is still considered by many urologists to be the "gold standard" to aid in the diagnosis of IC/PBS. Glomerulations, submucosal petechiae, are frequently seen after the irrigant pressure is released (see Figure 138.3). The capacity of the bladder at 80–100 cmH_2O is measured (anesthetic bladder capacity) and is usually reduced in the IC/PBS patient (normal anesthetic bladder capacity, 800–1200 mL; in IC/PBS usually <800 mL). The procedure has fallen out of favor with many urologists due to its lack of sensitivity and specificity.

When Hunner's ulcers are seen on cystoscopy (Figure 138.1), biopsies should be taken from these lesions to exclude carcinoma *in situ*. Only cystoscopy can accurately determine if inflammatory disease is present, as only approximately 30% of these patients show abnormalities on urinalysis that would otherwise prompt a cystoscopic examination [4].

Intravesical administration of concentrated potassium chloride, known as the potassium sensitivity test, is still used by some physicians to distinguish the source of pain in women with chronic pelvic pain and possible IC/PBS. The test can be easily performed in the office setting, but may provoke pain and it has a low diagnostic value (75% sensitivity) [42]. Another office-based test is the "anesthetic challenge." It is especially useful in patients presenting to the office with active pelvic pain, and includes installation of an intravesical anesthetic. Although there is no documentation about sensitivity and specificity, this test is reasonable and can yield useful information about likelihood of bladder-based pain, especially in patients who have a positive response.

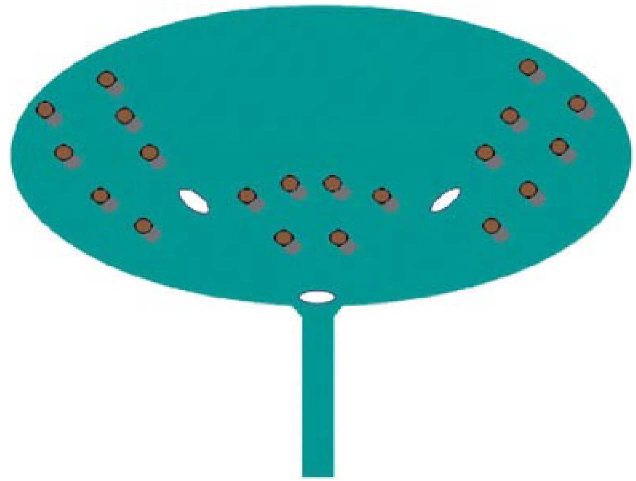

Figure 138.1 Location of injection sites for botulinum toxin (reproduced from Giannantoni *et al.* [67], with permission).

Management

One of the greatest challenges facing physicians and other healthcare providers is treating patients with IC/PBS. Even when urinary symptoms are addressed, many patients experience debilitating pelvic pain that is difficult to treat. Recognizing that the etiology of IC/PBS is likely multifactorial, patients are now often treated with multimodal therapy to address the different pain components. Lifestyle modifications, pharmacologic therapy, physical therapy, and surgical treatment options are available and often used in sequence or combination to offer patients the best symptom control possible [43].

Once diagnosed, patients are usually counseled and undergo a period of conservative management with careful assessment of the severity of symptoms. Patient education and empowerment are cornerstones of initial therapy. The patient should be reassured that although symptoms are bothersome, no life-threatening disease is present, and many therapies are available to control

symptoms. In patients with predominant frequency rather than pain, behavioral–modification therapy can be helpful. Diary keeping, controlled fluid intake, and pelvic floor muscle retraining can be combined to increase voiding intervals [11]. Expert opinion suggests that maintaining a normal lifestyle and increasing the quality of life for patients with IC/PBS can be augmented by stress reduction, exercise, and warm tub baths; however, no randomized trials are available to support or prove it. Acupuncture has been used in patients with IC/PBS as well as other chronic pain syndromes. Limited evidence exists that it is more effective than placebo and overall results with acupuncture have failed to show efficacy [44, 45].

Dietary modification is another first-line treatment modality that is often used. Many patients report symptom exacerbation by specific foods, including spicy foods and beverages including coffee, soda, and alcohol. A recent questionnaire-based study suggested that approximately 90% of IC/PBS patients have food sensitivities [46].

Initiation of therapy often starts with oral agents, such as amitriptyline, pentosan polysulfate (PPS) sodium, and hydroxyzine [36]. Amitriptyline is a tricyclic agent with four major pharmacologic actions: (1) blocks active transport at presynaptic nerve endings, affecting reuptake of serotonin and norepinephrine; (2) central and peripheral anticholinergic actions; (3) antihistaminic activity; and (4) sedative activity. The success rate reported with amitriptyline is 40–60% but most studies are based on a small number of patients. A large multicenter randomized controlled trial by Foster *et al*. showed that amitriptyline together with behavioral modification is no better than placebo when given to naïve patients with IC/PBS. Subgroup analysis demonstrated that patients who achieved and tolerated daily doses of 50 mg or greater did have improvement in symptoms [47]. Notable side effects include weight gain, constipation, urinary retention, dry mouth, and palpitations.

PPS is the only Food and Drug Administration (FDA)-approved agent, and a recent review of randomized controlled clinical trials showed it was "modestly beneficial" [48]. The drug presumably works by replenishing the defective GAG bladder mucosal layer. It is a synthetic, sulfated polysaccharide similar to the heparin sulfate analog, one of the GAGs normally found on the bladder surface [49]. The drug has also been found to be a potent inhibitor of allergic and nonimmune mast cell stimulation [50]. Sant *et al.* conducted a pilot clinical trial to evaluate the safety and efficacy of PPS. No benefit was observed compared to placebo, and adverse effects were reported to be minor and included reversible alopecia, diarrhea, headache, and skin rash. Limitations of this study included a small number of patients secondary to slow recruitment and it was most likely "underpowered" [51]. A meta-analysis by Hwang *et al*. showed the drug to be more efficacious than placebo in the treatment of pain, urgency, and frequency associated with IC/PBS [52]. The duration of therapy appears to be more important than the dosage. In a randomized, double-blind study by Nickel *et al*., different dosages were compared and patients were assessed for improvement of symptoms over 32 weeks. Patients showed similar improvement at dosages ranging from 300 to 900 mg and the overall response rate at 32 weeks was 50% [53].

Histamine H1 (hydroxyzine) and H2 (cimetidine) antagonists have shown some therapeutic effect in the treatment of IC/PBS patients. H1 receptor blockers can inhibit neuronal activation of mast cells and suppress degranulation. Evidence for the efficacy of hydroxyzine is limited and the maximum benefit demonstrated was a 40% reduction in symptoms [54]. Other data suggest no significant change in symptoms over placebo [51]. Cimetidine was developed as an oral treatment for peptic ulcer disease in the 1970s. Initial pilot trials showed efficacy of this agent in IC/PBS, and a subsequent study by Seshadri *et al*. supported these findings, reporting overall symptomatic relief in 66% of patients with IC/PBS [55]. The agent was also evaluated in a randomized trial in which patients taking cimetidine had a decrease in suprapubic pain and nocturia [56]. Limitations of this trial included a small sample size (n = 36), as well as a lack of qualitative change in the GAG layer or basement membrane of patients treated with cimetidine upon histologic evaluation of the bladder mucosa .

Minimally invasive procedures

Intravesical agents

The installation of intravesical agents provides a nonsurgical option for patients who fail conservative management, including oral medications, and may be considered one form of minimally invasive intervention. Treatment can be primary or in combination with other therapies. Several different agents are available, including DMSO, heparinoids, PPS, Bacillus Calmette–Guerin (BCG), clorpactin and, anesthetic agents. Some of the drugs are used in combination "cocktails."

DMSO, a lignin derivative, received FDA approval in 1978 for the treatment of IC/PBS. Its pharmacologic properties, including anti-inflammatory, analgesic, and muscle relaxant, make it a useful agent for the treatment of IC/PBS [57, 58]. Initially, the agent was used as a topical agent without success. It is now administered intravesically either as a single agent or as part of the DMSO "cocktail." Upon initial installation, patients may

experience a flare-up of pain and irritative voiding symptoms, and typically report improvement after the third or fourth installation. Reported response rates range from 50% to 90% [58, 59]. A combination of DMSO with a mixture containing agents such as heparin sodium, a steroid, an antibiotic, and sodium bicarbonate is used for some patients who fail single-agent therapy. However, only data from case reports suggest better patient tolerance and clinical improvement [60]. Side effects from DMSO other than the initial pain flare are reported and include garlic-like odor and taste, which is usually self-limiting. The drug is not recommended for use during pregnancy [58].

Some evidence exists that dysregulation of the immune system with an imbalance of T1 and T2 helper cells may have a role in the pathophysiology of IC/PBS. Small pilot studies have shown that patients with IC/PBS may benefit from intravesical BCG. The attenuated live agent stimulates T1 helper cells, leading to an increase in cytokine release. However, a randomized controlled trial could not show significant response rates when compared to placebo (21% vs 12%, $P = .06$) [61].

PPS, when used as an oral agent, achieves a low bladder concentration, resulting in a long lag time (3–6 months) before clinical improvement can be observed [62]. Davis *et al.* examined the agent's safety and efficacy in a randomized trial comparing oral therapy to a combination of oral and intravesical PPS [63]. Patients who received the combined regimen had a two-fold reduction in the severity of IC/PBS symptoms compared to those receiving oral therapy only ($P = .04$). Overall quality of life was also significantly improved, making combination therapy a treatment option for patients with moderate and severe IC/PBS. The incidence of adverse advents was comparable in both groups

Intravesical anesthetic agents may have a role in treating patients with IC/PBS. Local anesthetics are weak bases and absorption is limited in the human bladder. Henry *et al*. showed that alkalinization of urine in the bladder provides safe and predictable lidocaine absorption and enhanced anesthetic action, leading to decreased pain scores in patients with IC/PBS [64]. Deep local bladder mucosal anesthesia could potentially be used during bladder hydrodistention and possibly the excision or fulguration of small bladder lesions without the need for sedation. The effect of intravesical alkalinized lidocaine (PSD597) has recently been assessed in a randomized trial [65]. The study included 102 patients randomized from 19 centers, all with a diagnosis of IC/PBS. Preliminary results showed the agent to be effective, providing short-term amelioration of symptoms in most patients. The effects lasted beyond the treatment period and no significant adverse effects were noted

In addition to diagnostic cystoscopy, minimally invasive procedures used to treat IC/PBS are hydrodistention, injection of intravesical botulinum toxin (BTX), transurethral resection, coagulation of inflammatory lesions, and laser ablation.

Intravesical injection of BTX is one of the more recently introduced procedures, usually requiring rigid cystoscopy and injection of the bladder mucosa. BTX-A is used to treat muscle overactivity and spasticity. BTX-A is produced from different strains of the bacterium *Clostridium botulinum* and it has been approved by the FDA for the treatment of strabismus and facial dystonias. Multiple unlabeled indications promoted and supported by mounting literature include treatment of focal dystonias, achalasia, and cosmetic correction of wrinkles. Additionally, many different pain disorders have been treated (not FDA approved) with BTX-A, including those related to muscle hyperactivity (chronic pelvic pain, dystonia, myofascial pain, tension headache), as well as pain resulting from neurovascular disorders and spinal cord pathology. BTX is currently undergoing regulatory evaluation for urologic disorders (OAB, benign prostatic hyperplasia, and IC) and is to date not FDA approved for urologic use [66].

Data are accumulating to provide clinical evidence for the efficacy and safety of BTX for the treatment of IC [67, 68]. Giannantoni *et al*. showed that intravesical injection is effective for the short-term management of refractory painful bladder syndrome [67]. Patients received 200 U of BTX-A diluted in 20 mL of 0.9% sodium, using a rigid cystoscope and a flexible needle. A total of 10 U were given per injection site (Figure 138.2) and injections were administered to the lateral

Figure 138.2 Hunner's ulcer. These are almost always extratrigonal. They tend to bleed and tear easily with even small amounts of bladder filling. In this setting, hydrodistention would be unwise, as it would likely lead to bladder perforation.

bladder walls and the trigone submucosa. The beneficial effect progressively decreased over a few months and a repeat treatment course was required to achieve lasting symptom control. Patients reported significant improvement in daytime and night-time frequency, and improved bladder capacity was noted on follow-up cystometry. Pain recurred eventually in all patients and nine of 15 experienced short-term impaired detrusor contractility necessitating clean intermittent catheterization (CIC). Smith and Chancellor *et al*. reported on successful use of BTX for patients with IC [69]. The injections, however, were limited to the submucosa of the trigone and floor of the bladder. BTX treatment was given after hydrodistention during the first injection and together with protamine for better absorption at 6 months. All patients returned home the same day, catheterization was not necessary, and no patient experienced urinary retention or bladder hypocontractility. Overall 71% of patients had significant improvement in the cystitis symptom index score.

Complications such as urinary retention necessitating an indwelling Foley catheter or detrusor hypocontractility subjecting patients to temporary CIC are the most disconcerting features of this procedure and should be discussed with the patient. Limiting injections to the bladder floor and the trigone decreases the chance of diffuse chemodenervation of efferent nerves [69, 70], and possibly the risk of incomplete bladder emptying and urinary retention, which have been noted in trials where the lateral bladder wall was injected as well [67, 71]. Myofascial dysfunction associated with chronic pelvic pain is observed in up to 70% of patients with IC.

Injection of the pelvic floor with BTX can be part of a multidisciplinary approach when treating IC patients and may achieve better pain control than injection of the bladder alone [72].

Endoscopic procedures

Hydrodistention is often used with diagnostic cystoscopy during the initial evaluation but it can also be used for therapy in select patients. The procedure is usually performed under general or regional anesthesia. Glycine is the irrigant of choice and distention of the bladder is performed under direct cystoscopic vision to avoid overdistention and mucosal tearing. Distention is limited to short periods of time, typically 2–5 min at a pressure of 80–100 cmH_2O. Submucosal hemorrhage (glomerulations) is often seen after hydrodistention and typically resolves (Figure 138.3). In patients with Hunner's ulcer, a biopsy should be done to rule out the presence of malignancy and fulguration of ulcers should be performed. Hydrodistention should not be performed in these patients, to avoid profuse hemorrhage and possible bladder perforation. All biopsy and fulguration sites, and mucosal tear locations should be noted to avoid confusion of these lesions on future cystoscopic evaluation. Finally, instillation of 20–30 mL of a short-acting anesthetic agent, i.e. 1% lidocaine, may be helpful for patients undergoing hydrodistention to allow for faster recovery and decreased pain following the procedure.

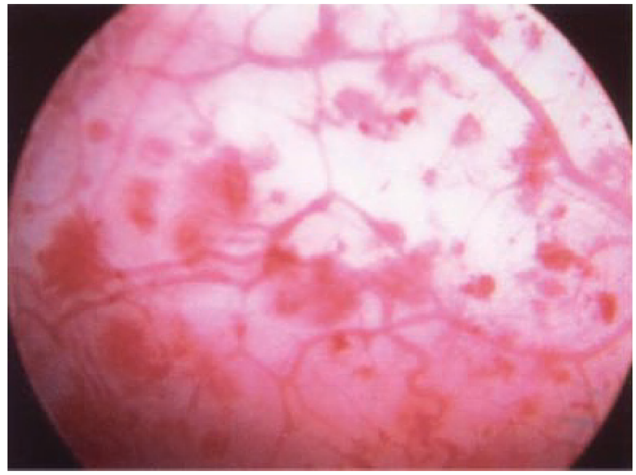

Figure 138.3 Glomerulations: submucosal hemorrhages typically seen in the interstitial cystitis/painful bladder syndrome patient after hydrodistention.

Reduction of symptoms ranges from 30% to 56% [73, 74]. Bladder distention was found to significantly reduce urine APF and HB-EGF toward normal.

The overall mechanism of symptom relief after hydrodistention is, however, still unknown [74], but theories include the increased elaboration of bladder surface mucin post hydrodistention or that hydrodistention actually causes a temporary nerve injury, resulting in some sensory impairment.

The procedure is considered safe; however, complications such as hematuria, bladder perforation, and bladder necrosis have been reported. Bladder perforation can usually be managed conservatively with catheter drainage. Vesical necrosis is a rare but serious complication of hydrodistention [75, 76].

For patients with severe IC/PBS and small bladder capacity, intravesical installation of hyaluronic acid can prolong the effect of bladder hydrodistention. The number of mean voids per day and bladder capacity were significantly improved for up to 9 month in patients receiving hyaluronic acid compared to treatment with hydrodistention only or hydrodistention with installation of heparin [77]. Similarly, intravesical injection of BTX at the time of hydrodistention has been found to reduce bladder pain. Liu *et al*. treated patients with 100–200 U of intravesically injected BTX followed by hydrodistention [68]. Treatment was considered successful if patients reported an improved quality-of-life

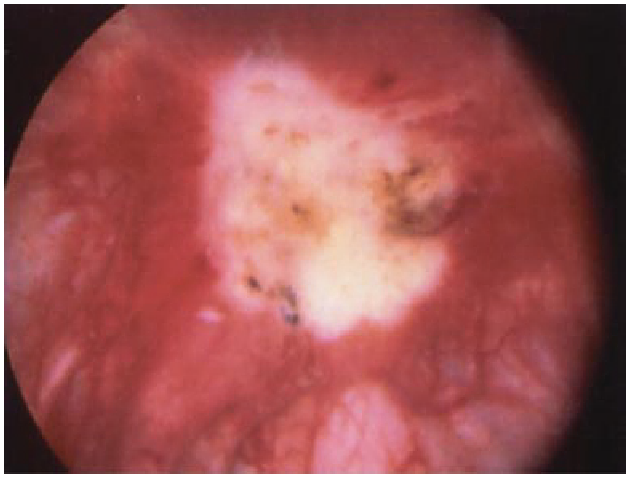

Figure 138.4 Hunner's ulcer after fulguration. Note the surrounding intense inflammatory reaction that develops rapidly after the applied energy. This is typically seen during the course of the ablative procedure.

index, complete resolution of bladder pain, and absence of voiding dysfunction. Partial response was recorded for patients with improved quality-of-life index, reduced pain (reduction of >2 points on the pain scale), and a greater than 25% reduction in urinary frequency. Patients reported symptomatic improvement at 3 month and the overall response rate was found to be 74%.

Classic or ulcerative IC/PBS affects about 5–10% of all patients with the disease and this subgroup may be amendable to endoscopic resection or fulguration of these lesions (Figure 138.4). In a retrospective analysis of 103 patients with classic IC/PBS, a total of 259 transurethral resections (TURs) of visible lesions were performed [78]. Ninety-two patients reported improvement of symptoms and in 40% of these relief lasted beyond 3 years.

Patients undergoing multiple procedures are at risk for bladder contracture and reduction of bladder compliance. Laser ablation can offer an alternative to TUR but comparison trials are lacking. Rofeim *et al*. conducted a prospective study investigating the use of the neodymium (Nd):YAG laser for IC [79]. A total of 24 patients were enrolled, treated, and prospectively followed up for 23 months. Low-energy (10–15 W) settings were used to ablate visible lesions in each patient. Response to treatment was noted 2–3 days after treatment. Patients reported a significant decrease in pain, frequency, and urgency. Fifty percent of patients needed only one treatment and had a mean response duration of 19 months. Retreatment is necessary in some patients and the treatment overall is not curative since ulcers recur. Possible benefits of laser ablation over electrocautery include less tissue damage to sounding bladder mucosa and hence less scarring. In the aforementioned trials, no complications developed; however, potential risks include bladder perforation, and bowel injury from forward scatter of the laser. These injuries may go undetected at the time of the procedure and postoperative assessment should include careful abdominal examination and electrolyte monitoring.

Conclusions

The diagnosis and management of IC/PBS remains challenging and the complexity of the disorder is only slowly being unraveled. No curative treatment has been established and effective treatment options are highly variable, depending on the individual patient. With increasing awareness and accumulation of basic and clinical research, future more effective treatment options may be discovered.

CHAPTER 139
Incision: Endoscopic Management of Urethral Stenoses

Jeremy B. Tonkin, Kurt A. McCammon & Gerald H. Jordan
Department of Urology, Eastern Virginia Medical School, Norfolk, VA, USA

Introduction

Endoscopic management of anterior urethral strictures and posterior urethral stenoses takes many forms. Urethral dilation and incision with a cold knife or laser urethrotomy are techniques familiar to all practicing urologists. The use of and indications for urethral stents are sometimes misunderstood. While these procedures have their role in the treatment of urethral disorders, their use should be predicated upon a thorough understanding of urethral anatomy, etiology of disease, and goals of treatment.

Herein, we review urethral anatomy with special attention to the difference in stenotic processes that occur in each segment. The types of available endoscopic techniques are discussed and outcomes in each selected process are reviewed. A stepwise approach to evaluating patients with urethral strictures/stenosis is suggested so that the practitioner can gain an adequate understanding of the disease process prior to initiating treatment.

It is imperative that, prior to undertaking a course of treatment, the differences in urethral processes and expected outcomes for endoscopic treatment techniques are understood. Both practitioner and patient should agree upon the expected outcomes of intervention prior to treatment. In only a select few processes will endoscopic management be expected to be durably successful and as such, open urethral reconstruction remains the gold standard for many conditions where the patient's goals are cure of the process.

Urethral anatomy

An understanding of the anatomic relationship of the urethra and investing corpus spongiosum is imperative for the urologist performing endoscopic surgery on the urethra.

The corpus spongiosum is the third erectile body of the penis which lies in the ventral groove between the two corpora cavernosa (Figure 139.1). It is surrounded by a tunica albuginea, which is thinner than the tunica albuginea of the corpora cavernosa. The urethra transverses the length of the penis within the corpus spongiosum, and at the distal end the erectile tissue expands to form the glans penis. The bulbous urethra is eccentrically placed in relation to the corpus spongiosum and is much closer to the dorsum of the penile structures. Distally, the penile urethra is more centrally placed within the corpus spongiosum. The meatus is slit-like in configuration with a vertical axis and is on the ventral aspect of the tip of the glans penis (Figure 139.2).

At the International Conferences of Urologic Disease (ICVD) at both Stockholm and Marrakesh the consensus opinion was to subdivide the urethra into seven separate distinct areas (Figure 139.3):

1. The meatus represents the interface between the epithelium of the glans penis and the urethral epithelium. Normally its axis is vertical and calibrates in some individuals up to 30F.

2. The fossa navicularis, contained within the spongy erectile tissue of the glans penis terminates at the meatus.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

This portion of the urethra is lined with stratified squamous epithelium.

3. The penile or pendulous urethra lies distal to the investment of the ischiocavernosus musculature but is invested by the corpus spongiosum. This section of the urethra maintains a constant lumen size roughly centered in the corpus spongiosum. It is lined with simple squamous epithelium.

4. The bulbous urethra is covered by the midline fusion of the ischiocavernosus musculature and is invested by the bulbospongiosus of the corpus spongiosum. It becomes larger and lies closer to the dorsal aspect of the corpus spongiosum, exiting from its dorsal surface before the posterior attachment of the bulbospongiosus to the perineal body. The bulbous urethra is lined

Figure 139.2 Cross-sections of the anterior urethra. (A) Bulbous urethra. The urethra is eccentrically placed in the corpus spongiosum. Proximally, the corpora cavernosa have split into individual crura, with the urethra lying against the triangular ligament. (B) In the shaft of the penis, the urethra is more centrally placed in relation to the corpus spongiosum, and the corpora cavernosa are intimately fused, separated only by septal fibers. (C) At the coronal margin, the urethra remains relatively centrally placed, and the corpora cavernosa are fused, again separated by septal fibers. The spongy tissue of the corpus spongiosum has become incorporated as the deep tissues of the glans. (D) The fossa navicularis widens somewhat in caliber and is totally surrounded by the spongy erectile tissue of the glans penis. The urethra here is relatively ventrally placed in relation to the body of the corpus spongiosum (reproduced from Jordan, G.H. Complications of interventional techniques of urethral stricture disease: Direct visual internal urethrotomy, stents and laser. In: Carson, C., ed. *Topics in Clinical Urology: Complications of Interventional Techniques*. New York, Igaku-Shoin, 1996, pp. 86–94, with permission).

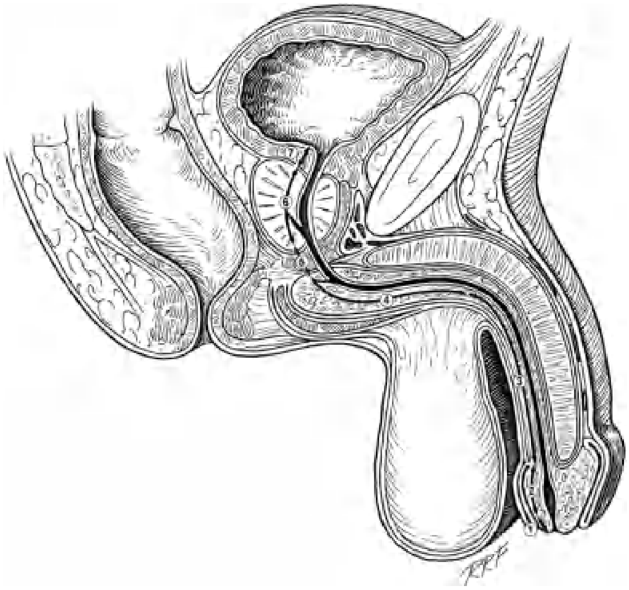

Figure 139.3 Sagittal section of the pelvis. The urethra is subdivided into the following sections: 1, meatus; 2, fossa navicularis; 3, pendulous or penile urethra; 4, bulbous urethra; 5, membranous urethra; 6, prostatic urethra; and 7, bladder neck. By common usage, the divisions of the meatus, fossa navicularis, pendulous urethra, and bulbous urethra compose the anterior urethra; and the divisions of the membranous urethra, prostatic urethra, and bladder neck compose the posterior urethra (modified from Devine, C.J. Jr, Angermeier, K.W. Anatomy of the penis and male perineum. *AUA Update Ser* 1994;8:11).

distally with squamous epithelium that gradually changes to the transitional epithelium found in the membranous urethra as it swings upward [1].

5. The membranous urethra is the portion that traverses the perineal pouch and is surrounded by the external urethral sphincter. This segment of the urethra is unattached to fixed structures and has the distinction of being the only portion of the male urethra that is not invested by another structure. It is lined with a delicate transitional epithelium.

6. The prostatic urethra, in common use, is the portion of the urethra that lies proximal to the membranous urethra and is mostly surrounded by the prostatic stromal and glandular tissue. Its epithelium is continuous with that of the trigone and bladder.

7. The bladder neck is the location of the bladder neck musculature, variably surrounded by intravesical protrusion of the prostate. Its epithelium is also contiguous with that of the trigone and bladder.

Urethral stricture disease

The term urethral stricture refers to anterior urethral disease, a scarring process involving the spongy erectile tissue of the corpus spongiosum, also referred to as spongiofibrosis (Figure 139.4). Under the urethral epithelium lies the spongy erectile tissue of the corpus spongiosum and in some cases, scarring can extend through the tissues of the corpus spongiosum and into adjacent tissues. As the scar contracts, it reduces the diameter of the urethral lumen. The normal urethra measures approximately 30F and its diameter is approximatly10 mm. The calculated luminal area is approximately 78 mm^2. If scarring has resulted in a urethra that measures 15F, the lumen is only 55 mm^2, a 29% reduction. Scar contraction caused by anterior urethral stricture disease can be markedly asymptomatic early in the process, but as the scarring process and contracture continue and the urethral lumen is further reduced, marked voiding symptoms can develop. This process may occur anywhere within the anterior urethra.

Posterior urethral "strictures" are, in fact, not referred to as strictures at all. By consensus of the ICUD conferences, the term stricture is limited to the anterior urethra; while distraction defects are a subcategory of those processes of the membranous urethra associated with pelvic fracture. Other narrowing of the posterior urethra, urethral contractures, or stenosis [2, 3] are processes that do not involve spongiofibrosis and are thus referred to as stenoses rather than strictures. As with anterior urethral strictures, posterior urethral stenosis is an obliterative process that has resulted in fibrosis and luminal narrowing. This process has often been initiated by a distraction injury, whether due to trauma or surgical manipulation. Although in some cases these stenoses can be lengthy, the actual process involving the tissues of the urethra is usually well confined. Conditions that result in posterior urethral stenosis include membranous urethral stenosis, prostatic urethral stenosis, bladder neck contracture, vesicourethral distraction, and posterior urethral distraction defects.

Etiology

Any process that injures the urethral epithelium and/or the underlying corpus spongiosum to the point that healing results in a scar causes a urethral stricture or stenosis. Anterior urethral strictures most commonly result from trauma, infection, inflammatory conditions or urethral manipulation. In many cases, the inciting event goes unrecognized by the patient until they present with obstructive voiding symptoms.

Traumatic injuries such as straddle injuries are a common example. Penetrating injuries, such as gunshot or stab wounds, may be appropriately treated initially and still lead to the development of delayed stricture disease. Iatrogenic trauma is a known etiology of urethral strictures, but with the development of smaller scopes and the recognition of the importance of careful technique, fewer of these cases are now being seen.

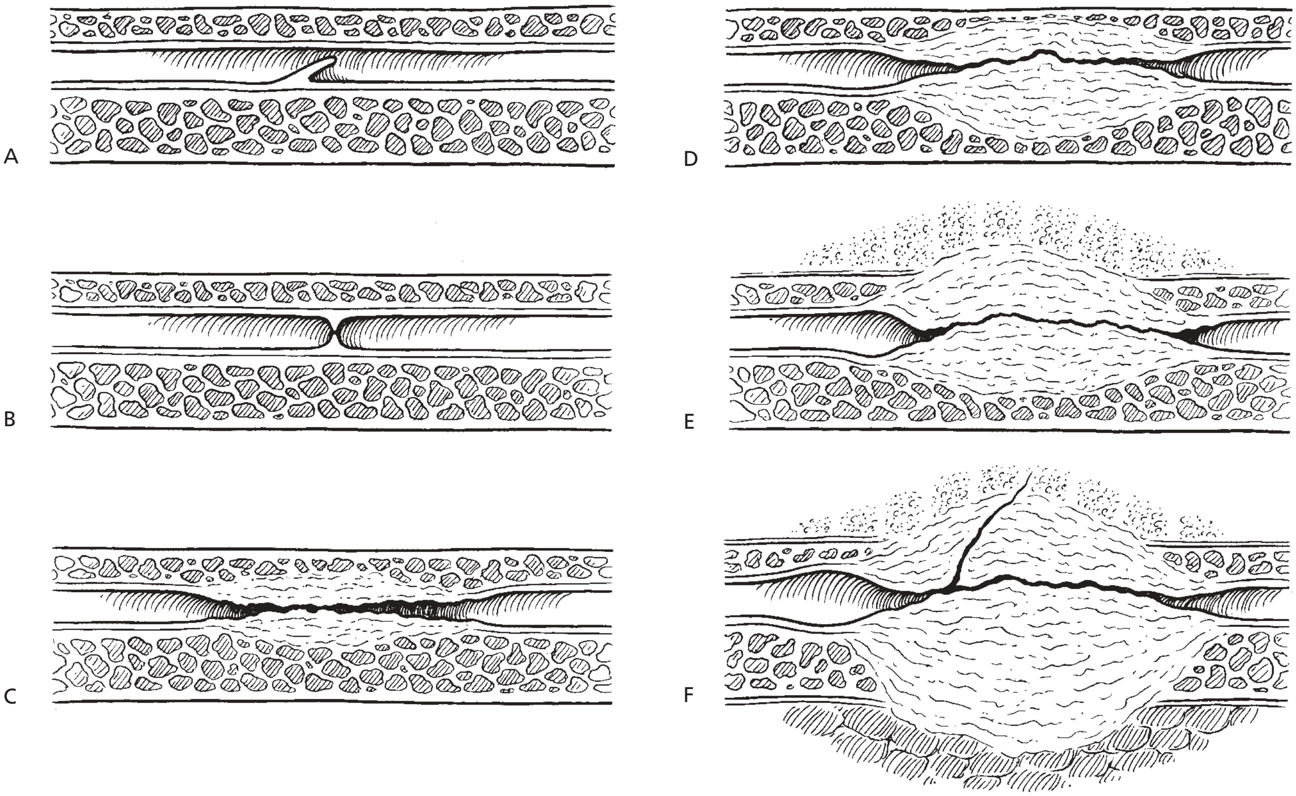

Figure 139.4 Anatomy of anterior urethral strictures includes, in most cases, underlying spongiofibrosis. (A) Mucosal fold;
(B) iris constriction; (C) full-thickness involvement with minimal fibrosis in the spongy tissue; (D) full-thickness spongiofibrosis; (E) inflammation and fibrosis involving tissues outside the corpus spongiosum; (F) complex stricture complicated by a fistula (reproduced from Jordan, G.H. Management of anterior urethral stricture disease. *Probl Urol* 1987;1:199–225, with permission).

The inflammatory dermatosis lichen sclerosus is a commonly seen disease process in patients with anterior urethral strictures. This condition behaves much differently from traumatic strictures, recurring quite readily, and thus requires special consideration when contemplating treatment options. Typically, the initial presentation is that of meatal stenosis associated with skin inflammation of the glans penis and prepuce. The inflammation then progresses proximally, perhaps due to distal obstruction, high pressure voiding, and subsequent microextravasation of urine into the corpus spongiosum and glands of Littre.

Infectious strictures associated with gonorrhea, which were commonly seen in the past, are now much less common. With the advent of more effective antibiotics and widely available medical care, gonococcal urethritis today rarely progresses to urethral stricture disease. As we understand the processes currently, nonspecific urethritis either due to Chlamydia or other organisms does not lead to urethral strictures.

The condition of idiopathic urethrorrhagia has in the past been felt to be related to urethral stricture because children were endoscoped for diagnosis. In years past, before the minification of endoscopes, it was felt that those stricture were iatrogenic. However, now there is accumulating evidence that the entity itself can cause proximal bulbous urethral stricture disease [4].

Finally, there are the so-called congenital strictures. These strictures occur in infants and young children, are short in length, noninflammatory, and not associated with potential for traumatic etiology. They are the rarest of all strictures.

Posterior urethral stenoses and anterior urethral strictures have many similar causes, although there are also several etiologies specific to the posterior urethra. Membranous strictures may result from urethral manipulation or radiation. Larger French resectoscopes, such as are used for transurethral resection (TUR) procedures, may cause tearing of the membranous urethra as it departs the corpus spongiosum. Brachytherapy seeds placed distal to the apex of the prostate can lead to radiation damage to this portion of the urethra as well. Prostatic urethral stenosis is rarely encountered, although when seen it may result from iatrogenic endoscopic manipulation of the prostate or radiotherapy. Bladder neck stenosis is seen commonly after TUR or radical prostatectomy. It is usually manifest as a

short-length stenosis of varying caliber at the junction of the urethra and bladder. In some instances, endoscopic procedures for prostatic enlargement (whether traditional TUR or laser prostatectomy) are performed when there is an unrecognized underlying element of voiding dysfunction. In these cases, the symptoms that prompted treatment will certainly recur. Bladder neck stenosis typically responds well to endoscopic management, by gentle dilation or incision using cold knife, electrocautery or laser techniques. A more severe form of bladder neck stenosis termed vesicourethral distraction stenosis can be a devastating consequence of radical prostatectomy. It occurs when the vesicourethral anastomosis is disrupted and leads to a longer defect that is quite resistant to endoscopic treatment. Posterior urethral distraction defects are commonly seen with anterior pelvic arch fractures. It has been classically taught that these fractures cause the prostatic apex to separate from the membranous urethra in the manner in which an apple is removed from its stalk. Newer data, however, show that these injuries typically occur more distally than the level of the prostatic apex [5, 6]. The level of the distraction defect is usually found just proximal to the departure of the bulbous urethra from the membranous urethra, and thus spares the external urinary sphincter. As in a vesicourethral distraction, this injury leads to extensive fibrosis interposed between the two distracted ends of the urethra and is resistant to endoscopic management.

Diagnosis and evaluation

Patients who have urethral strictures most often present with obstructive voiding symptoms, urinary tract infections (UTIs), hematuria, dysuria, and/or urinary retention. Compensatory hypertrophy of the detrusor may initially allow patients to void through a narrowed urethral lumen with few symptoms. Additionally, some degree of decreased urethral caliber may not significantly affect the flow dynamics. Patients may not develop significant symptoms until a reduced urethral caliber of 10–12F is reached. Many of these patients will relate an insidious onset of voiding symptoms before progressing to obstructive symptoms or complete obstruction.

First, it is important to question the patient as to the history of trauma, especially straddle trauma. A history of urethral infection, previous urethral, prostate or bladder surgeries, and previous catheterizations should be noted. A thorough genital examination should also be performed. Stigmata of hypospadias, lichen sclerosis, previous surgical interventions, and spongiofibrosis may be found. These clues revealed by history and physical examination may give the practitioner additional information as to the etiology of the disease process. This is quite important, as strictures of different etiologies may behave differently when treated.

Prior to any invasive manipulation or investigation, the state of the urine with regards to presence of microorganisms should be assessed, if possible. When the patient is in retention, this may not be feasible and broad-spectrum antibiotic coverage should be given prior to any attempt at catheterization, endoscopy or retrograde urethrography. Urine should be sent for culture when obtained. If it is a nonemergent situation, care should be taken to sterilize the urine prior to proceeding with investigation. In cases of colonization, such as exists in patients with chronic indwelling suprapubic cystostomy catheters, prophylactic doses of culture-specific antibiotics should be given. This is done not with the intent to eradicate colonization, but rather to prevent septicemia during the manipulation.

Passing a urethral catheter is a commonly attempted procedure when a patient cannot void. If the catheter does not pass, the nature of the obstruction is determined by dynamic retrograde urethrography. Many cases are managed with acute dilation, but this may not be in the best interest of the patient. When there is doubt, the nature of the stricture should be determined. A suprapubic cystostomy catheter can be used to treat the acute retention and give time to plan more appropriate treatment. No longer is blind passage of filiforms or blind dilation considered acceptable. The anatomy of the stricture must be determined either through advanced imaging or flexible endoscopy, which at the least, allows the stricture to be visualized and a guidewire to be passed under direct vision through the lumen. In this manner, dilation is not done "blindly," but with the wire to direct the dilators into the true lumen.

In addition to etiology, the location, length, depth, and density of the stricture (spongiofibrosis) or stenosis must be accurately determined in order to develop a workable treatment plan. The length and location of the stricture can be determined with traditional radiography, urethroscopy, and/or ultrasonography. Some feel that the absolute length of spongiofibrosis may not be evident by ultrasound evaluation alone. Contrast-enhanced studies may be further complemented by the addition of ultrasound studies and together these are accurate in determining the length of narrow-caliber annularity [7]. Contrast studies of the urethra are best carried out by or under the direct supervision of the surgeon responsible for treatment of the patient. The depth and density of the scar in the spongy tissue are difficult to determine, but are subjectively best evaluated by physical examination, contrast-enhanced studies that show the appearance of the urethra, and elasticity and appearance of the mucosa by endoscopy. While magnetic resonance imaging (MRI) and ultrasonography have been used to help characterize the degree of

spongiofibrosis and location of the defect, we find these studies to rarely influence the treatment plan developed with traditional radiography and endoscopy.

At our center, imaging includes retrograde urethrography as well as voiding cystourethrography. The patient is placed in a steep lateral oblique position as anteroposterior images often can miss lesions or misrepresent their length. Even with gentle technique, extravasation during retrograde urethrography is possible in patients in whom the urethra is markedly inflamed. For this reason, contrast studies should be carried out with contrast that is suitable for intravenous injection and used either directly from the bottle or diluted according to the manufacturer's guidelines. It should also be understood that during contrast-enhanced urethrography, more than one projection may be necessary to visualize the stricture. Realtime ultrasound evaluation of the urethra after it has been filled with a lubricating jelly or saline has been described by Morey and McAninch [7, 8]. It is a misconception, however, that ultrasonography always directly visualizes the spongiofibrosis. Morey and McAninch, however, believe that ultrasonography of the bulbous urethra possibly more accurately determines the length of the stricture, which is important in considering an anastomotic repair [7, 8].

An initial endoscopic examination with the flexible cystoscope may be necessary after the contrast studies to evaluate the urothelium and assess the degree of spongiofibrosis. A pediatric cytoscope is a very useful tool to help traverse an area of narrow-caliber disease without having to dilate it, as dilation may not be ultimately beneficial. Care should be taken to avoid inciting inflammation of a particularly narrow stricture by passage of the pediatric endoscope. This may cause temporary edema and lead to an episode of acute retention. In the patient who cannot void and who has a suprapubic tube, combined contrast studies with endoscopy are helpful in defining the stricture anatomy (Figure 139.5). This evaluation allows delineation of the proximal point of the stricture by endoscopy, and the distal point by retrograde urethrography done simultaneously.

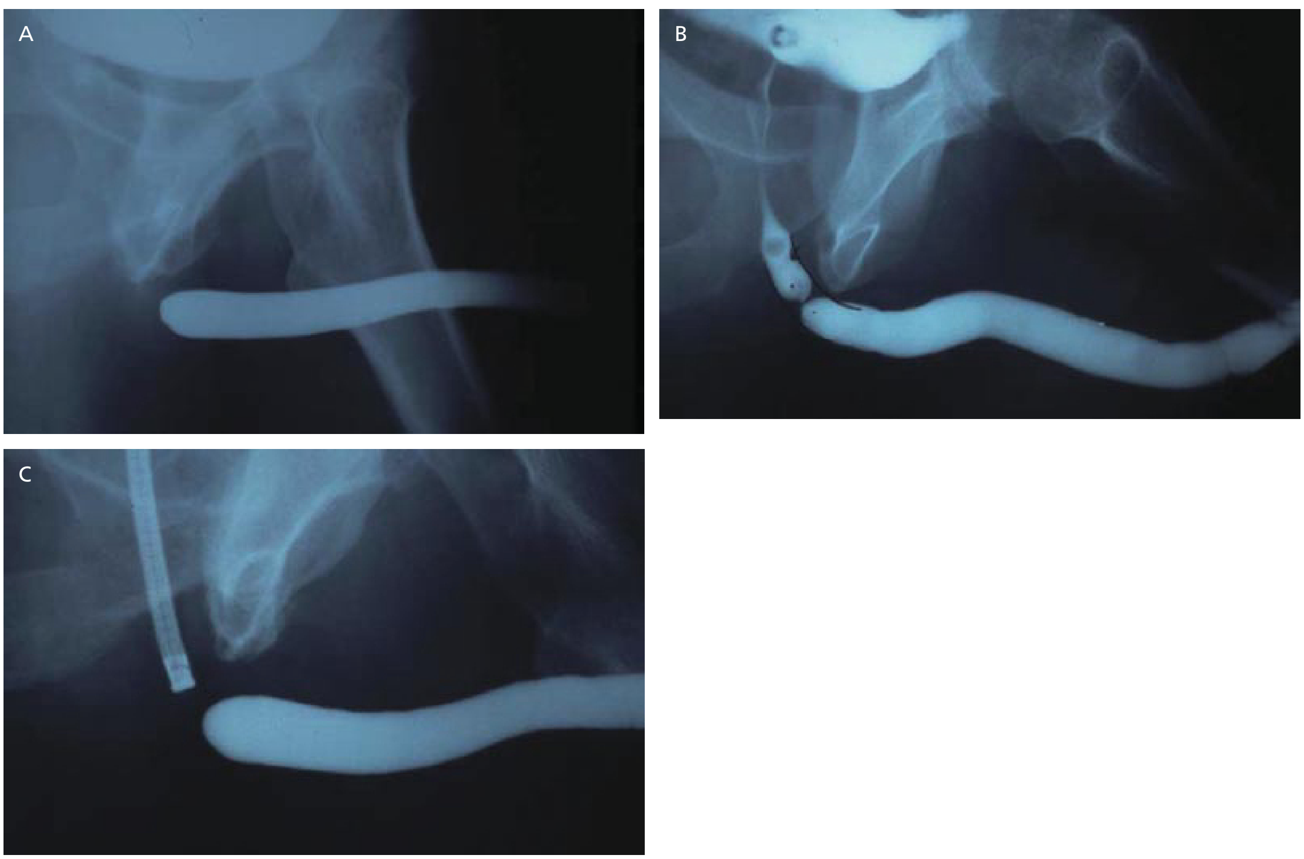

Figure 139.5 Series of radiographs demonstrating the usefulness of the combination of contrast enhancement with endoscopy. (A) A retrograde urethrogram shows a totally obliterative process involving the proximal bulbous urethra. (B) The patient was successful in relaxing to void; however, there is a suggestion of a wide-caliber annular area proximal to the obliterative process of the bulbous urethra. (C) Endoscopy through the suprapubic cystostomy tube clarifies the anatomy of the proximal urethra and demonstrates the length of the obliterative process.

In selected patients, in whom long-standing outlet obstruction is suspected or the degree of urethral obstruction does not correlate with symptoms, urodynamic studies may be warranted prior to treatment. Compensatory detrusor hypertrophy in cases of long-standing outlet obstruction may lead to myogenic detrusor failure. In this case, the patient may not void despite correction of the obstructive process. Correction may facilitate intermittent catheterization and thus may be appropriate, but this is an outcome that should be clearly understood, if possible, by the patient prior to treatment. Likewise, when the degree of symptoms is more severe than would be expected from the degree of luminal narrowing, suspicion is raised for bladder dysfunction or concomitant prostatic obstruction. Video urodynamics may be helpful to elucidate the level of obstruction, especially if prostatic or bladder neck hypertrophy is present. In these cases, treatment of the urethral narrowing alone may not alleviate obstructive symptoms. Additionally, medical treatment of the prostate or bladder neck may decrease or resolve obstructive symptoms without the need for treatment of the urethral pathology.

Treatment

Both the patient and the physician must have a good understanding of the goal of treatment before the treatment choice is made. To this end, treatment options should be discussed with the patient, with care taken to emphasize the anticipated outcome with regard to palliation versus cure. Some patients may prefer palliative stricture management and choose to have periodic dilations in the office, at home, or in the hospital, rather than undergo technically detailed open surgery. Others may have cure as a goal and choose open surgical management. The information gained in the evaluation of the stricture is imperative in discussing treatments and expected outcomes with the patient. Also, a thorough knowledge of the etiology of the process is needed for counseling on risk of recurrence. Many well-described reconstructive procedures utilized today have long-term success rates in excess of 90% and may be used to repair many common types of strictures.

Dilation

Filiform dilators have been used for years. The filiform leader is passed initially through the stricture. If the straight tip does not pass, there are spiral tips that may allow passage. The safest way to pass the filiform leader is under direct vision. Also available are a myriad of metal and plastic dilators that may be passed in a similar fashion. Again, blind dilation should be discouraged [9].

The least traumatic method would be soft dilation techniques over multiple treatment sessions. We believe the safest method currently available is the use of urethral balloon dilation. These catheters may be attached to a filiform tip or passed over a guidewire with an integral Coudé tip. For the patient's initial dilation we prefer cystoscopy under anesthesia to allow for placement of a wire which facilitates safe passage of the balloon. In this setting the stricture is truly dilated. A home balloon obturation protocol can then be performed by the patient with the goal of maintaining the operative dilation. This minimizes the amount of repetitive trauma to the urethra and allows the healing process to stabilize, while being periodically opposed by the home balloon protocol. We prefer to have the patient use a steroid cream as lubricant for the balloon to decrease urethral inflammation. Additionally, oral antibiotic therapy may be used as an anti-inflammatory agent. Initially, the patient starts the obturations several times daily, then daily, then weekly, and then steadily decreasing the frequency as the process allows. This protocol allows for treatment of most types of urethral stricture/stenosis, although as previously stated, distraction defects of the posterior urethra are very difficult to manage in this fashion.

Meatal dilation in cases of meatal stenosis secondary to lichen sclerosis has also been proven to be an effective management strategy. It is quite easy for patients to perform home dilations using a graduated dilator lubricated with steroid cream. The patient must be thoroughly counseled on proper technique and the goals of dilation if this is to be successful. Frequent, nonaggressive episodes of dilation are favored over periodic forceful episodes. In addition to limiting trauma, the patient will usually find this to be more comfortable, as very little pain and no bleeding should be encountered. By limiting the amount of distal obstruction, proximal dilation and extravasation should also be minimized, thus decreasing proximal inflammation and possibly stricture formation. With initial persistence and patience, many patients find that eventually the meatal process stabilizes and only infrequent interventions are needed.

Dilation has been shown to be equal to direct vision internal urethrotomy (DVIU). Steenkamp *et al*. performed a randomized prospective trial comparing DVIU to filiform dilation in 210 men with urethral strictures [9]. Their results show a 16% greater recurrence rate at 36 months in the dilation group compared to the DVIU group, and a 10% higher recurrence rate at 48 months. Stormont *et al*., in a retrospective review of 199 nonrandomized patients with short bulbar strictures treated with dilation or DVIU, showed that the success rates were equal. At 3 years the success rate for the dilation group was 65% compared to 68% for the DVIU group

[10]. Due to the fact this was a nonrandomized retrospective review, there was some selection bias which cannot be excluded.

Complications associated with urethral dilations include cystitis, epididymitis, hemorrhage, recurrent urethral stricture, and false passage.

Internal urethrotomy

Internal urethrotomy refers to a procedure that opens the stricture by incising it transurethrally. The procedure involves incising through the scar to healthy tissue to allow the scar to expand with the goal that it will heal with a larger caliber. The process of incision essentially sets off a race between epithelialization and wound contracture. If the incised areas epithelialize, i.e. heal by secondary intent, before the wound contracts, then the area will stay open. If not, then the stricture recurs. As with dilation, the goal is to minimize trauma to the unaffected adjacent tissues.

The technique of a cold knife urethrotomy is a relatively simple procedure using a 0° or 12° scope with a 19 or 21F sheath. It is important to use isotonic fluid, usually normal saline, to limit the risk of hyponatremia if there is extravasation, and possibly the isotonic fluid effect on the tissues during the procedure may be less injurious. A glidewire or ureteral catheter should first be passed through the stricture into the bladder. Something should always be passed through the area before incision to maintain identification of the true lumen. Many surgeons will make the incision at the 12 o'clock position, although we question this because of the location of the urethra within the corpus spongiosum (see Figure 139.2). On cross-section of the corpus spongiosum, the thinnest portion is the anterior aspect between 10 o'clock and 2 o'clock. Therefore, a deep incision could penetrate through the corpus spongiosum into the intracrural space, or corpus spongiosum if the incision is further distal. These incisions into the corpora cavernosa have been associated with erectile dysfunction, likely due to veno-occlusive dysfunction. If it is felt that the spongiofibrosis is deep, an internal urethrotomy will not be curative. We prefer using multiple small radial incisions at 10, 2 and 6 o'clock, without cutting too deep into the corpus spongiosum.

Cure rates following DVIU initially were considered to be 80% or above, and this initially caused an increase in the use of internal urethrotomy [11]. Additionally, many practitioners were more familiar with this type of management as compared to open urethral reconstruction. The idea of a "reconstructive ladder" was thus popularized. Many considered that it was appropriate to perform multiple endoscopic procedures on recurrent strictures *in lieu* of opting for open reconstruction. This has since been proven to be faulty logic. Subsequent studies have borne out the issues of endoscopic success and the effect of multiple endoscopic treatments on open reconstruction. Success rates following DVIU have been shown to vary between 35% and 90%, possibly dependent on the length of stricture, previous treatments, and length of follow-up assessed.

The nature of the strictures being treated with internal urethrotomy has been poorly reported and with various endpoint parameters. This makes comparative assessment difficult because the literature is not clear as to the goal of internal urethrotomy. For many, internal urethrotomy is considered successful if it offers temporary relief. Santucci and McAninch reported curative success rates to be approximately 20% using actuarial techniques [12]. Pansadoro and Emiliozzi as well as others have shown that DVIU is curative in 30–35% [13]. Their study did not show any long-term success for strictures outside of the bulbar urethra. Data show that strictures in the bulbar urethra that are less than 1.5 cm in length and are not associated with dense, deep spongiofibrosis can be managed with internal urethrotomy with 74% success rates. It has been shown in multiple studies that success of urethral reconstruction is diminished by multiple prior urethral dilations or internal urethrotomies [14–16, Boccon-Gibod, L. Personnel communication, 2005]. Some have shown a single internal urethrotomy prior to an open urethral reconstruction to be cost-effective [17]. Others have refuted this finding and have found urethrotomy to lengthen the stricture and make subsequent reconstruction more difficult [18]. In any event, a single attempt at urethrotomy is probably warranted if all of the available criteria favor the chance of success. If these criteria are not favorable, it may not be cost-effective or of any benefit to the patient.

Recurrence of the stricture is the most common complication associated with internal urethrotomy. Complication rates following internal urethrotomy range from 8% to 27%. Complications associated with internal urethrotomy include dysuria, UTI, septicemia, minor bleeding, retention, scrotal abscess, extravasation, urinary sepsis, and epididymo-orchitis. Erectile dysfunction has also been reported as a complication in up to 11% of patients after an internal urethrotomy. Possible causes are fibrosis after extravasation with infection or injury to the cavernous nerves with deep incision. Other more uncommon complications include a urethral–internal pudendal artery fistula leading to high-flow priapism, severe hemorrhage, and urosepticemia. These unusual complications are usually associated with aggressive internal urethrotomy.

Since the success rate with internal urethrotomy is so poor, several techniques have been employed to oppose the wound contraction. One option is to leave an indwelling Foley catheter for 6 weeks after urethrotomy in

the hope that the urethra will mold around the catheter as it heals. Studies have shown that the failure rates with this technique are equal to those when a catheter is left for 3–7 days. Another option used to oppose the wound contraction forces is home self-catheterization. The catheter is left in place for 3–7 days and once removed, the patient is started on a urethral catheterization program. This usually requires more catheterizations in the first 3–6 months, but the number tapers thereafter. It is our experience that once the patient stops the self-catheterization, the stricture recurs, but this technique can effectively manage motivated patients. However, as already discussed, protocols using catheters or balloon obturation can successfully manage patients.

It has been shown that the length of follow-up as well as length and location of the stricture are of utmost importance in determining success. Boccon-Gibod and Le Portz had a 56% cure rate at 6 months and 43% at 12 months, but only 25% at 2 years [11]. Albers *et al*. confirmed the lower success rates over time, with a success rate of 95% at 6 months but only 55% at 38 months [15]. With a repeat urethrotomy the success rates appear to decrease. One study has shown a success rate of 75% with the initial treatment but only 45% for a secondary treatment. Length of stricture also has a significant effect on recurrence. Steenkamp *et al.* showed success rates at 12 months for strictures greater than 4 cm to be less than 20% compared to 40% for strictures of less than 2 cm [9]. Finally, a number of studies have shown higher success rates with strictures in the bulbar urethra compared to the penile urethra.

Dilations and/or urethrotomies may be used as part of a palliative strategy almost anywhere in the urethra. With some persistence on the part of a motivated patient and a favorable stricture etiology, some strictures may only need periodic maintenance. Conditions such as lichen sclerosis, which have a high propensity for recurrence, are often treated in this fashion as few if any "curative" options have been discovered. If either of these methods, however, is being used with a notion of curative intent, the characteristics of the process must be carefully evaluated. The highest reported success rate is in short (<1.5 cm) mucosal strictures of the proximal bulbous urethra, as mentioned above. Attempts to manage more distal anterior urethral strictures or stenoses of the posterior urethra will likely have no durable result. Additionally, if a single attempt at dilation or urethrotomy fails, subsequent attempts should also be expected to fail. Particularly dismal are the results after dilation or incision of a vesicourethral distraction defect or posterior urethral distraction defect. Incision of a bladder neck stenosis after TUR or radical prostatectomy may be the only exception to the rule for posterior urethral stenoses, in that these do respond well to endoscopic management [19].

Lasers

The ideal laser for use in the treatment of urethral strictures is one that totally vaporizes the scar, exhibits negligible peripheral tissue destruction, is not absorbed by water, and is easily propagated along the fiber. As with previously described treatment modalities, care should be taken to minimize injury to adjacent tissues as this may worsen the disease process. There are several types of lasers used for the treatment of urethral stricture disease, including carbon dioxide, argon, KTP, neodymium (Nd):YAG, holmium:YAG, and excimer lasers. Although the carbon dioxide laser appears to be ideally suited, it must be used with a gas cystoscope, which carries the potential risk of carbon dioxide embolus.

For both the argon and Nd:YAG lasers, the mode of action is thermal necrosis, which has significant potential for peripheral tissue injury rather than vaporization. The Nd:YAG laser is also used with a bare fiber in contact mode, which carries a risk of forward scatter. Used in the contact mode, the YAG energy is transferred to a sapphire tip which will obliterate the scar by vaporization of the tissue. There are no data showing improved results for obliteration compared to DVIU.

A KTP laser is essentially a Nd:YAG laser that has passed through a KTP crystal, resulting in a reduced depth of penetration. The internal urethrotomy with the KTP laser is done by passing the fiber over the scar tissue. The holmium:YAG laser has properties similar to the KTP laser and provides both direct cutting and vaporization with minimal scatter. Numerous studies have shown the holmium:YAG laser to be safe in the treatment of urethral strictures, although success rates appear to be comparable to DVIU performed with a "cold knife" [20, 21].

The excimer laser is a vaporizing laser with little forward scatter or peripheral tissue necrosis. Little experience with this laser has been reported but its characteristics warrant further investigation.

The results of laser urethrotomy are mixed, but with the advent of new lasers future data may show improved results. A laser with perfect characteristics for treating urethral stricture disease does not seem to exist at this time. Currently, no data exist to show superiority of laser urethrotomy over other techniques. Its indication for usage is similar to that of dilation or cold knife urethrotomy, as discussed above. Short bulbous strictures, prostatic urethral stenoses, and bladder neck stenoses are the most likely to respond to laser urethrotomy. Small to no durable results should be expected from utilizing laser urethrotomy in more distal anterior urethral strictures, vesicourethral distraction defects or posterior urethral distraction defects.

Urethral stents

As discussed above, when wounds heal, the healing process may lead to contraction. Urethral stents (removable or permanent) can be used to oppose the forces of wound contraction after internal urethrotomy or dilation.

The UroLume® stent (American Medical Systems, Minnetonka, MN, USA) is a permanent, biocompatible, nonmagnetic superalloy woven into a tubular mesh that is self-expanding to 42F. After being deployed, it is incorporated into the wall of the urethra and the corpus spongiosum. The UroLume stent is used in patients with short bulbar strictures of less than 3 cm in length and at least 1 cm from the external sphincter. Available data show that the stent is best employed for short strictures associated with minimal spongiofibrosis. Initial results for the UroLume stent were encouraging with retreatment rates decreasing from 75.3% to 14.3% after insertion in 105 patients who were followed for 1 year [22]. Of the 179 patients originally enrolled, 24 patients completed 11-year follow-up, and the overall success rate at 11 years was less than 30% [23]. This was confirmed in a study with 10-year follow-up from the Netherlands, which reported that only two of the 15 patients implanted were satisfied [24].

Complications associated with permanently implantable stents are unique. Many of these complications occur when the stents are placed outside the bulbous urethra. This is especially true in the pendulous urethra or when the stent is used for a vesicourethral or posterior urethral distraction defect. These complications may include pain with intercourse and sitting, perineal discomfort, and painful erections. Other complications include recurrent stricture, hyperplastic tissue growth, migration of the stent, recurrent UTIs, dysuria, calculus formation, and hematuria. Contraindications to UroLume placement include previous substitution urethral reconstruction where skin has been incorporated into the reconstruction. These patients will experience a virulent hypertrophic reaction of the skin, which can lead to a severe functional recurrence of the stricture. Other patients who are poor candidates for the UroLume stent are those whose strictures are associated with deep spongiofibrosis, which includes patients with straddle injuries and urethral distraction injuries. We consider that UroLume is indicated only for patients with short bulbar strictures whose medical problems preclude open urethral reconstruction.

The concept of a temporary stent is appealing compared to a permanent stent. The concept is to leave the stent in place long enough to act as a mold until stabilization of the wound, preventing scar contraction during the healing process. The Memokath urethral stent (PNN Medical, Kvistgaard, Denmark) is made of nitinol and is currently available in Europe, but not in the USA (where a large randomized trial has just been completed). The Memokath is a thermoexpandable stent. Once placed in position, prewarmed saline is flushed through the stent and urethra, expanding the stent and the bell-shaped ends, which secures the stent in place. The main body of the stent is 24F, and with the bells 44F. The tight spiral structure of the stent prevents urothelial ingrowth

Conclusions

Initial evaluation of a patient with a urethral stricture/stenosis should include a thorough history and physical examination. Length of duration of symptoms, history of trauma, infection or surgery should be noted. The genitalia should be inspected for scars, inflammatory changes, and stigmata of previous treatment, and the entire course of the corpus spongiosum should be palpated and assessed for fibrosis. Thorough radiographic and endoscopic evaluation should also be performed. After determining the length, location, depth, density, and proposed etiology of the process, the patient should be counseled as to palliative versus curative intent of any intervention. In cases of acute urinary retention, thought should be given to placement of a suprapubic cystostomy catheter *in lieu* of dilation in selected patients.

Only in very carefully selected processes should endoscopic attempts at management be considered to have a reasonable chance at cure. While both dilation and DVIU have similar rates of success, these rates are only favorable in short, superficial, noninflammatory, proximal bulbous strictures. Any other attempts should be considered palliative. Multiple attempts should not be made in patients who are considered candidates for an open reconstructive procedure. Certain types of strictures, such as those of the meatus and fossa navicularis, may respond well to interval dilation. Other processes, such as posterior urethral or vesicourethral distraction injuries, typically do not. That said, endoscopic management may be very reasonable for a variety of patients and is appropriate as long as the goals are clearly stated and understood.

No laser or urethral stent is currently available in the USA that has been shown to drastically revolutionize endoscopic management of urethral stricture/stenosis. Further study is needed to identify and replicate the characteristics of these tools that provide ideal minimally invasive management of this often difficult disease process. For many patients who desire a curative procedure, open surgical reconstruction remains the gold standard.

CHAPTER 140

Bladder Neck Contracture Following Radical Prostatectomy

Timothy B. Boone

Department of Urology, The Methodist Hospital, Houston, TX, USA

Introduction

The formation of a bladder neck contracture (BNC), or anastomotic contracture as it is often called, following radical prostatectomy can be a devastating complication. There is no consensus regarding the definition of BNC, which makes an accurate complication rate hard to derive from the literature. The incidence is reported to range from 0.5% to 32%, and the definition of a BNC ranges from urinary retention to a pinhole circular narrowing of the urethra above the external sphincter [1–6]. In many studies, the inability to pass a 16F cystoscope defines a BNC.

The onset of a BNC is usually heralded by a diminished force of stream, urinary frequency, progressive straining to void or frank urinary retention. In most cases the symptoms occur 6–8 weeks after surgery. As Webb *et al*. point out in their publication on laparoscopic versus robot-assisted radical prostatectomy-induced BNCs, "this [timeline] is consistent with the normal healing process of fibrosis and wound contracture" [6]. Urethral catheter placement is attempted and when this fails, flexible urethroscopy is performed to confirm the BNC and visualize the caliber and condition of the narrowed urethral lumen at the urethral anastomosis.

Incidence

The incidence of urethral stricture after primary treatment for prostate cancer was examined utilizing the CaPSURE database in 2007 [7]. Radical prostatectomy was performed in 3310 men with 277 (8.4%) developing a urethral stricture requiring treatment. In most cases the initial therapy was urethral dilation and in 42% of cases the BNC code was used and entered into the database. Even though academic practices report lower incidences of BNC, ranging from 2.5 to 4.8%, reviews of ICD-9 and CPT codes from the Medicare database note a BNC rate of 22%, including for high-volume surgeons (>60 radical prostatectomies/year) [8]. The incidence of BNC following open radical retropubic prostatectomy is higher than the reported incidence emerging from the robot-assisted radical prostatectomy literature (see below).

In 1994 Jonler *et al*. surveyed 93 consecutive men for complications following radical prostatectomy, with responses from 92% of the patients [9]. Treatment of a BNC was reported in 20% of the men and more than half of the group had undergone more than one procedure. More recent large contemporary single-surgeon series have reported BNC rates below 10% following open radical prostatectomy. The BNC incidence for Kirby was reported to be 9.4% following radical prostatectomy in 510 consecutive men [10]. In the majority of cases a single dilation of the BNC was effective, with only 19% requiring more treatment, along with five men utilizing self-catheterization for several months. In 2009 Erickson *et al*. reported the latest update on Catalona's single-surgeon series of 4132 men undergoing open radical retropubic prostatectomy [11]. The overall incidence of BNC was 2.5% with a lower rate (1%) in the last 500 patients undergoing surgery.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 140.1 Multifactorial causes of bladder neck contracture following radical prostatectomy.

Technical	Clinical
Surgical experience	Urinary tract infection
Vest technique	Previous TURP
"Stomatization"	Cigarette smoking
Anastomotic urine leak	Coronary artery disease
Non-nerve sparing RRP	Diabetes mellitus
Bladder neck reconstruction "racket handle"	Hypertension
	Radiation therapy
Pelvic hematoma	Hypertrophic scar former
Large volume blood loss	Age >70 years
Suture type and technique	Obesity
Duration of indwelling catheter	Higher clinical stage
	Higher PSA
Caliber of reconstructed BN	Radiation therapy

RRP, radical retropubic prostatectomy; TURP, transurethral resection of the prostate; PSA, prostate-specific antigen.

Etiology

The exact cause of BNC is not known and multiple factors have been associated with its development (Table 140.1). Providing direct apposition of the urethral mucosa to the bladder neck and avoiding a "gap," especially at the posterior margin, was the technical objective behind mucosal eversion or "stomatization" described in the open radical prostatectomy literature. "A well-vascularized and water-tight suture line obviously is ideal for optimal healing of the anastomosis" [10]. Borboroglu *et al.* hypothesized that men with potential microvascular compromise could be at increased risk, and implicated several comorbidites increasing the risk of BNC after radical prostatectomy [12]. Poor healing of the anastomosis and scar formation secondary to local ischemia from microvascular disease was the central theory behind their prospective study. In their series of 467 men undergoing radical prostatectomy, 11.1% developed a BNC. Smoking at the time of radical prostatectomy in 62 men was associated with a 26% BNC rate, compared to 9% in the nonsmokers, a statistically significant difference. In addition, they showed higher rates of BNC in men with coronary artery disease, hypertension, and diabetes mellitus. Current smokers and men with coronary artery disease were shown clearly to be at much higher risk for BNC following radical prostatectomy. Other clinical factors to consider include age greater than 70 years and obesity, both of which were significant risk factors for BNC [7].

Early urinary retention following radical prostatectomy has been shown to be an early risk predictor for BNC formation [13]. From 1998 to 2004, investigators at Michigan studied 1289 men following radical prostatectomy. Men presenting with urinary retention occurring within the first week after catheter removal were 4.7 times more likely to develop a symptomatic urethral stricture (94% BNC). The overall population had a 9.9% risk of BNC, while 36.4% of those with early retention formed urethral strictures. The authors recommended educating postoperative patients with early retention about their increased risk of developing an anastomotic stricture by explaining the early signs and symptoms of obstruction.

Technical factors

An overall incidence of BNC following radical prostatectomy of 20% was reported by Levy *et al*. who retrospectively reviewed 143 cases, focusing on their anastomotic technique and postoperative evaluation with voiding cystourethrograms [14]. Three surgical techniques were explored, including radical perineal prostatectomy (15 patients), radical retropubic prostatectomy (93 patients) with a direct anastomosis and bladder neck reconstruction, and radical retropubic prostatectomy with a modified Vest anastomosis (35 patients). Voiding cystourethrograms were performed at 3 weeks to evaluate for the presence or absence of contrast extravasation at the anastomosis. The Vest technique resulted in the lowest incidence of urinary extravasation (6%), but had the highest BNC rate (27%). The lack of direct mucosal apposition with the Vest method led to the abandonment of this technique. Furthermore, the authors remarked that urinary extravasation was a sign of a persistent anastomotic gap and there was no increase in BNC incidence as long as the catheter was left in place until the urinary extravasation resolved.

The caliber of the anastomosis and the technique for reapproximating the urethra to the bladder are proving to be important factors to consider in the prevention of BNC. Many surgeons considered that a bladder neck-sparing operation would preserve continence, so attention was paid to preservation of the bladder neck as it was dissected away from the base of the prostate to yield a small-caliber anastomosis. Most contemporary series dispute this concept and have embraced a nonsparing approach to the reconstruction to allow tailoring of the bladder neck to a wider-caliber anastomosis. Eastham *et al.* modified their surgical technique in 1990 to embrace a 24–26F tailored bladder neck, which lowered their BNC rate from 20% to 6%; they remarked that the bladder neck played little if any role in the long-term continence rate in 390 men treated by open radical prostatectomy when compared to 191 men treated before the introduction of the modification [15]. Catalona *et al.* increased the size of their reconstructed bladder neck from 18F to 24F in 1870 consecutive radical retropubic prostatectomy patients and their BNC rate dropped

from 10% to 1% [16]. In addition, many surgeons are concerned about higher positive margin rates with bladder-neck sparing. Tapering or tightening the anastomosis appears to increase the BNC rate and few studies have demonstrated any advantage in terms of improved continence from using a narrowed anastomosis.

One early tenet of the anastomotic surgical technique was mucosal eversion sutures or "stomatization." For experienced surgeons, BNC rates have declined with experience. However, the recent introduction of laparoscopic and robot-assisted radical prostatectomy has markedly lowered the BNC rates. In fact, Forster *et al.* embraced a continuous anastomotic technique, based on this emerging trend, in their open radical prostatectomy patients and avoided mucosal eversion in 39 consecutive patients [17]. There were no BNCs in their series. Harpster and Brien described their series of 72 patients utilizing a continuous running anastomosis following open prostatectomy [18]. With a mean follow-up of 31 months there were no reported BNCs and in most men the catheter was removed 4–6 days following prostatectomy. There is compelling evidence, based on large series of laparoscopic and robot-assisted radical prostatectomies, that mucosal eversion and interrupted sutures are not necessary and may actually contribute to higher BNC rates.

Failure of primary radiotherapy, whether external beam radiation alone or with brachytherapy, followed by salvage prostatectomy leads to a much higher incidence of BNCs. Gotto *et al.* compared a series of men undergoing open radical prostatectomy versus failed primary radiotherapy followed by open salvage radical prostatectomy and noted BNC rates of 3% versus 26%, respectively [19]. Furthermore, the number of procedures to manage the BNC and the invasiveness of the treatment was significantly greater in the salvage group of men in whom radiotherapy failed to cure their prostate cancer. The BNC rate was elevated much like that seen in men with prior transurethral resection of the prostate (TURP) followed by radical prostatectomy.

Management

Prevention of a BNC is the best method of management. While most BNCs present early following catheter removal and can be managed with a single urethral dilation, those that are dense and recurrent can be a major source of life-long morbidity. Unfortunately, the presence of a BNC is often associated with some degree of post prostatectomy incontinence. Evaluation of the BNC should include a urinalysis and postvoid residual urine measurement. The presence of a urinary tract infection should be treated prior to any instrumentation.

The initial treatment of a BNC is usually dilation with urethral sounds or filiforms and followers in the office.

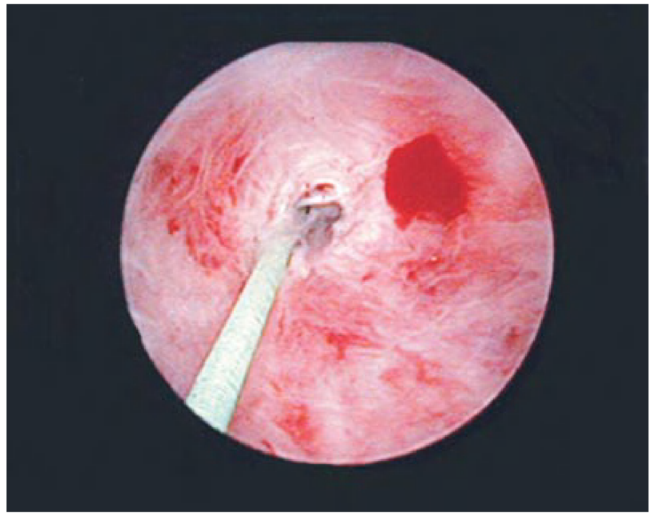

Figure 140.1 Tight anastomotic contracture with guidewire in the lumen.

Visualization of the urethral obstruction with flexible cystoscopy should precede blind dilation whenever possible (Figure 140.1). Post-prostatectomy sphincter strictures can be mistaken for a BNC and "they are the most difficult of all strictures to manage effectively and the prime consideration must be the preservation of its all-important residual intrinsic sphincteric function (upon which the patient's continence depends), rather than the definitive resolution of the stricture itself" [20]. Without careful inspection under direct vision, it is not possible to differentiate a sphincteric stricture from a BNC. Along with a much higher risk of inducing sphincteric incontinence, the tendency to restenose is higher with sphincteric strictures since tonic closure of the muscle narrows the urethral lumen during bladder storage. Careful and limited dilation of the sphincteric stricture is the method of choice as opposed to internal urethrotomy.

In most cases, a single urethral dilation manages the BNC with resolution of symptoms and incomplete voiding [21]. Repeated office-based BNC dilation is not warranted. With the exception of soft self-catheterization to maintain urethral patency, especially when a stricture involves the urethral sphincter, routine dilation rarely "cures" the BNC. Failure of initial urethral dilation is followed by operative intervention with cold-knife incision of the BNC. Radial incisions, through the scarified urethra down to healthy tissue, at three sites are the preferred method for opening the BNC. The use of simultaneous transurethral steroid injection into the stricture has not been studied in a randomized fashion, although several investigators have touted the use of triamcinolone acetonide (200 mg) for this purpose. One small clinical trial investigated botulinum toxin A

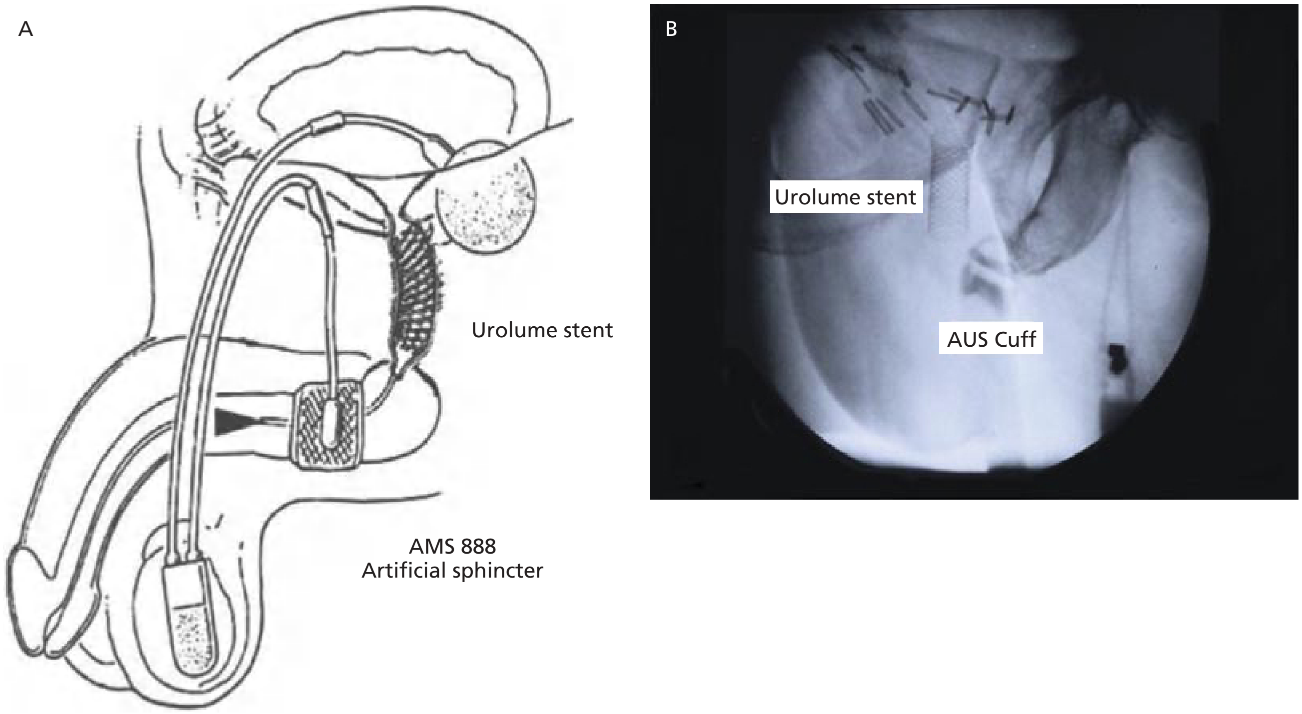

Figure 140.2 (A, B) Urethral stent at the bladder neck with artificial urinary sphincter (AUS).

injection in men with bladder neck contractures and showed some early positive results where the toxin helped maintain patency of the anastomosis [22].

Some investigators prefer laser incision of the BNC over use of the cold knife, although there are no studies supporting one method over the other. Recently, Eltahawy *et al.* managed recurrent anastomotic contractures following radical prostatectomy with holmium laser incision and steroid injection [23]. The success rate ("well healed and widely patent") for recurrent anastomotic strictures in 24 men treated with this method was 83% at a mean of 2 years. Artificial urinary sphincters were implanted in 11 men, illustrating the common association of urinary incontinence with BNC.

If initial urethrotomy fails to manage the BNC, many clinicians resect the BNC to try and maintain patency. We prefer to avoid heat whenever possible in the treatment of a BNC, as this can induce more scar formation than was present with the initial BNC. The failure of BNC resection to manage recurrent BNCs effectively led us to consider using the UroLume® stent (American Medical Systems, Minnetonka, MN, USA) in the late 1990s. The UroLume stent was approved for use in prostate-mediated outlet obstruction, detrusor–sphincter dyssynergia, and short strictures in the bulbous urethra, but not for BNCs. For men faced with urinary diversion as the next step to manage their recurrent BNC-induced obstruction, we offer the UroLume stent as a potential option.

Elliott and Boone reported their series of nine men with recurrent BNC and concurrent post-prostatectomy incontinence treated by initial incision and UroLume stent placement followed by delayed insertion of an artificial urinary sphincter [24] (Figures 140.2). The men were followed for a mean of 17.5 months. One patient had a recurrent BNC while the others maintained urethral patency and showed marked improvement in continence after artificial sphincter placement. Webster *et al.* at Duke utilized a similar staged approach in nine men with recurrent BNC in whom the UroLume stent was implanted followed by an artificial sphincter once the stent had epithelialized and the BNC was open and stable [25]. A larger series of 25 men with recurrent BNC and incontinence managed by UroLume stent placement was reported by Elliott *et al.* at the Mayo Clinic [26], with a median follow-up of 2.9 years. A single stent was adequate in 52% of the patients, while multiple stents (two to four) were used in the remainder, with an overall patency rate of 76%. Artificial urinary sphincters were placed in 23 men with quality-of-life improvement noted in 92%. This staged approach should be used with caution as the stents are difficult to remove and regrowth of scar through the stent is possible. Proper deployment of the stent across the BNC can be difficult in cases where the anastomotic stricture is fixed behind the pubis, preventing proper alignment of the deployment tool prior to release of the stent to span the entire BNC.

Careful patient selection and experience with UroLume stent placement are mandatory before considering this method to manage the severe recurrent BNC.

Surgical repair with excision of the BNC in an open setting usually requires a combined open approach from above and below. Very few reports have tackled this difficult surgical approach. McAninch *et al.* described their results with anastomotic urethroplasty in 19 men, with an overall success rate of 73% [27]. Nine men, in whom concurrent radiotherapy was employed, opted for stent placement for fear of poor healing with an open procedure. A combined open approach to complex bladder neck–prostatic contractures was described by Theodorou *et al*. with a mean operative time of over 4 h, which included artificial urinary sphincter placement to correct the inevitable incontinence with this surgical approach [28].

In our experience, most patients with severe and recurrent BNC who decline stent placement followed by an artificial urinary sphincter opt for urinary diversion. In selected cases, we offer a Mitrofanoff procedure with or without augmentation cystoplasty instead of ileal conduit diversion. The BNC is allowed to close and in most cases the patients remain dry per urethra.

CHAPTER 141
Bioinjectables for SUI (Stress Urinary Incontinence)

John J. Smith III[1] & Simone Crivellaro[2]

[1]Department of Urology, Wake Forest University School of Medicine, Wake Forest Institute of Regenerative Medicine, Winston-Salem, NC, USA

[2]Urology Department, Azienda Ospedaliero-Universitaria di Udine, Udine, Italy

Introduction

Recent improvements in our understanding of the underlying pathophysiologic mechanisms responsible for stress urinary incontinence (SUI) in women have led to the development of innovative new surgical methods for its treatment. Many are less invasive than prior techniques and appear to offer improved safety and shorter hospital stay, while maintaining the efficacy of traditional open incontinence surgery. Procedures using injectable periurethral bulking agents characterize this current trend toward less invasive surgical treatments. However, some recent reviews have shown a decline in the use of bulking agents [1].

History

Bulking agents have a long medical history in fields outside of urology. They have been used for gastroesophageal reflux, scars and wrinkles, as well as for patients with glottic insufficiency [2, 3]. Urethral bulking agents have been used to treat stress incontinence since 1983 when Murless used sodium morrhuate or cod liver oil as a sclerosing agent in the anterior vaginal wall of 20 patients, attempting to create an inflammatory response. Others used similar agents, but until 1973 this approach was seldom used. Berg [5] and Politano *et al.* [6] popularized the use of polytetrafluoroethylene (Teflon) through the 1970s. However, urethral bulking only became popular following the Food and Drug Administration (FDA) approval of bovine glutaraldehyde cross-linked collagen (Contigen).

Mechanism of action

Injectable agents appear to augment the urethral wall and thereby increase urethral resistance. The resulting improvement in urinary incontinence is not associated with a corresponding increase in voiding dysfunction. This is because the "seal" that is formed by restoring mucosal coaptation does not occlude the urethra. The urethra maintains the ability to funnel and open, with no change in detrusor pressure to initiate a flow. Interestingly, most agents are placed short of the bladder neck, within the smooth muscle layer in the zone of the continence mechanism.

Klarskov and Lose measured pressure and cross-sectional area in the urethra of women with SUI and mixed incontinence before and after urethral injection therapy, using a pressure profile reflectometer [7]. This novel technique detected a more significant increase in squeezing opening pressures in patients who had subjectively noted an effect. They suggested that injection therapy functions as a central filler volume that increases the length of muscle fibers and thereby the power of the urethral sphincter. The external sphincter consists of muscle fibers, collagen, vessels, and nerves, with a central component compressing the lumen [8]. An

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

increased central filler volume will augment the sarcomere length of muscle fibers, strengthening muscle power up to a sarcomere length of 2.2 μm [9, 10].

Patient selection

The index patient for bulking should have demonstrated stress incontinence and evidence of intrinsic sphincter deficiency (ISD). While there exists some argument over a fixed versus a mobile urethra, most would agree that a relatively fixed urethra (nonradiated) may respond well to bulking. The patient with hypermobility may have some improvement, but usually the shearing force of a cough is too great to maintain dryness if mobility exists.

Traditionally, urethral bulking agents have been specifically indicated for SUI secondary to poor urethral sphincter function. This usually means a low Valsalva leak point pressure and limited urethral mobility. This indication is based on the fact that support is a key factor to consider in urethral bulking. Specifically, if there is poor vaginal support and significant mobility of the bladder neck/urethral complex, other options usually have better results. However, because bulking agents were originally considered to have greatest utility in these kinds of patients and subsequent reimbursement followed along those lines, it was some time before patients with hypermobility were studied in the USA in any detail. Herschorn *et al.* in Toronto demonstrated that the patient with hypermobility could derive benefit [11, 12]. In fact, no significant difference in outcomes was seen in patients with or without hypermobility in their studies. Interestingly, patients with hypermobility required less collagen for a successful outcome. Monga *et al.* reported on 60 women with genuine stress incontinence and urethral excursion ("mobility") of up to 25 mm [13]. Objective cure rates (according to urodynamic assessment) were 61% at 3 months and 48% at 24 months. Subjective success rates were 86% and 68% at 3 months and 24 months, respectively. A logical conclusion derived from these studies is that ISD can exist in the presence of hypermobility and that this alone should not be a criterion for exclusion from bulking therapy. There of course exists a gray area, where the patient and physician agree to use these agents fully anticipating a partial improvement in an otherwise poor surgical candidate.

Finally, in addition to physical examination, urodynamic studies need to be performed to document a low leak point pressure, as well as to rule out other sources of incontinence. Some reimbursement can be predicated on the documented leak point pressure. Ideally, video provides a look at the bladder neck and proximal urethra, confirming low urethral resistance.

Techniques

There have been numerous approaches to placement of urethral bulking agents, including intraurethral or transurethral, periurethral, and even transvaginal [14–16]. The two most common routes are intraurethral or periurethral, and the former is by far the most popular. Yet, two transurethral techniques evolved for a short time: the obvious visual approach and a "blind" technique. The nonendoscopic approach was designed ostensibly to eliminate operator variability. First described by Henalla *et al.*, a device was developed to control the placement of the injected material in predetermined areas [17]. This technique is rarely used today in the USA.

Faerber *et al*. reviewed the outcomes and differences between the transurethral and periurethral routes of injection [14]. There were no statistically significant differences in outcome. In a prospective study by Schulz *et al*., the authors concluded that both periurethral and transurethral methods were comparable [15]. However, the amount of material utilized was much greater in the periurethral group, which would of course drive the expense of the procedure upward.

Ideally, an injection system scope or a female urethroscope should be used for the procedure. After the bladder is drained, the scope is placed mid urethra. Most techniques describe needle placement at 4 and 8 o'clock with a submucosal injection. The trial with Macroplastique (see below) added an injection at the 6 o'clock position. Many patients require additional treatments and various waiting periods are required for each unique agent.

Postoperatively, a small amount of bleeding or bulking agent leakage can be noted for 1–2 days. Retention can occur and should be treated with 24-h catheterization with a small 8–10F Foley or clean intermittent catheter technique. It is usually self-limiting. If prolonged retention is apparent, then a suprapubic tube should be considered to avoid crossing the urethra which has been treated. Moreover, it is not uncommon to have temporary irritative urinary symptoms. Stothers *et al*. reported a 12.6% incidence of *de novo* urge incontinence in a large prospective trial [18].

Materials

The ideal injectable agent primarily should be safe, i.e. biocompatible, nonimmunologic, and hypoallergenic. It should retain its bulking characteristics for a prolonged interval and not biodegrade or migrate, but it should also be easily explanted or degraded if necessary. Additionally, it should be easy to prepare and implant.

Glutaraldeyde cross-linked bovine collagen

Of the many options, glutaraldehyde cross-linked bovine collagen (Contigen™) is the most studied and used bulking agent. It is a highly purified suspension of bovine collagen in normal saline containing 95% type 1 collagen and 5% type 3 collagen cross-linked with glutaraldehyde for stability, durability, and reduction in hypersensitivity. A skin test is required prior to injection and a recommended 30 days must pass before treatment. The procedure is simple and easy, and in our hands almost exclusively done in the office. It can be relatively expensive over time however, and at least one analysis by Berman and Kreder suggested an uncomplicated sling is more cost-effective [19]. Early results showed promise with very high cure and improvement rates [11], but enthusiasm has been tempered by long-term cure rates of 14–25% and improvement rates of 25–60% [20]. Complications have been divided into early and late [18]. The most common are urgency, transient retention, and hematuria, all usually self-limiting. Other late complications have included delayed skin reactions, particularly with reintroduction of collagen, and arthralgia. Serious complications, such as pulmonary emboli and osteitis pubis have also been reported [21, 22]. The possibility exists for an allergic response to the bovine protein, since a sensitizing pretreatment skin test is performed, although this is reduced by cross-linking. A very small number of patients will have a positive skin test, precluding them from treatment with this agent. The material, however, remains the most widely used injectable for SUI in the world.

Carbon-coated zirconium beads

Carbon-coated zirconium beads (Durasphere™) is a sterile, nonpyrogenic injectable bulking material composed of pyrolytic carbon-coated graphite beads suspended in a 97% water, 3% beta-glucan carrier gel. It is inert and nonimmunogenic, and therefore does not require skin testing.

In a head-to-head trial, Durasphere and collagen were randomized to similar patients. The Durasphere group showed an improvement of 1 or more Stamey grades in 80% of patients compared to 69% in the collagen group. While substantial on the surface, the difference did not meet statistical significance [23].

Recently re-engineered via its carrying gel for delivery, it is now available as Durasphere EXP and has an optimized bead size of 90–212 µm (it is known that macrophages can phagocytize particles of less than 80 µm). Once in this system, the beads theoretically can be transported throughout the body. Durasphere beads should not migrate because of their size. It is possible that the zurconium beads found in lymphatics and other places most often result from high pressure injection. Durasphere is safe and has no risk of allergy. Results have been comparable to those with collagen, but the immediate complications with it are slightly higher, as reflected in the rate of urinary retention, but this rarely persists or needs surgical intervention [24].

Silicone polymers

Silicone (Microimplants, Macroplastique, and Bioplastique) is a soft, flexible irregular material made of vulcanized polydimethylsiloxane macroparticles or simple silicone rubber. The silicone particles are inert, biocompatible, nonbiodegradeable, and nontetratogenic. The mean particle size is 100–300 µm, limiting the chances of migration. The material, however, still must be injected with a special injection system because of its high viscosity. The material was recently approved by the FDA for treatment in SUI.

Reported cure and improvements rates are 60% and 80%, respectively [25, 26]. Complications are similar to those with other agents and include transient hematuria, retention, and UTI. Barrett and others have expressed concern about small particle migration, but this is certainly not common [27].

In a multicenter randomized trial between Macroplastique and collagen, 61.5% of the former agent improved by 1 or more Stamey grades, as opposed to 48% of the collagen group. A total of 36.9% of patients in the Macroplastique group were dry compared with 24.8% of the collagen patients [28].

Calcium hydroxyapatite

Calcium hydroxyapatite (Coaptite) is a synthetic injectable implant composed of smooth calcium hydroxylapatite bioceramic microspheres that have a diameter range of 75–125 µm, suspended in an aqueous gel carrier. A normal constituent of bone, it is also nonimmunogenic, and was previously used in dental and orthopedic surgery. A 12-month prospective, randomized, comparative, multicenter, single-blind, parallel, clinical trial of calcium hydroxyapatite and collagen for soft tissue augmentation of the urethral sphincter in the treatment of SUI enrolled 296 women. Essentially comparable results, 63% and 57% improvement, respectively, were reported. Approved by the FDA in November of 2005, it is used for the treatment of ISD. As yet, at least two serious side effects have occurred: one erosion through the vaginal wall and one injection which dissected into the bladder, causing a tissue bridge to form. Lastly, urethral prolapse has been reported in a delayed fashion months after injection [29].

Ethylene vinyl alcohol copolymer

Initially approved by the FDA in 2004, this injectable was composed of ethylene vinyl alcohol (EVOH) copolymer in dimethyl sulfoxide (DMSO) as a permanent hypoallergenic implant. The material would expand after injection into the urethra, where the DMSO would diffuse out, allowing the EVOH to precipitate as a hydrophilic material. Unfortunately, many patients had dysuria and other complications.

A large multicenter trial was reported by Dmochowski *et al*. with encouraging early results [30]. However, the complications of dysuria and pain later developed into erosions and inflammation often necessitating surgical correction [31]. More recently, experience of the use of EVOH copolymer (Uryx/Tegress) came to a halt because of serious adverse events reported to the FDA. The injectable material previously used to inject arteriovenous malformations was withdrawn from the market in December of 2006, just 2 years after its introduction.

Polyacrylamide hydrogel

Bulkamid urethral bulking agent is a cross-linked synthetic polymer. The peculiarity of this agent is that it is homogeneous as it does not contain any particles. In the original clinical trial on the use of this agent by Lose *et al*., eight patients (38%) were subjectively dry and a further nine (43%) improved. Objectively, urine leakage/24 h decreased by 93% and the number of incontinence episodes decreased by 87% [32]. Quality-of-life measures improved significantly in all domains other than general health perception. There were no significant changes in urodynamic variables. Treatment-related adverse events were recorded in 16 women. Urinary tract infection (UTI; 10 cases) and urinary retention (five cases) were the most common.

Other agents

There have been attempts to use other materials, including dermal collagen implants, autologous fat, and even autologous chondrocytes [33].

Outcomes

Generally speaking, one of the main goals of bulking is to increase the quality of life of patients. A literature review by Chapple *et al*. concluded that quality-of-life improvement after urethral injections appears to be significant and is comparable to that obtained with surgery, despite the observation of superior objective surgical efficacy [34]. The outcomes and adverse effects for each specific material are summarized in Table 141.1.

Table 141.1 Reported (A) adverse events and (B) outcome with bulking agents.

A

	FDA approval	Number of adverse events	Ongoing sales
Contigen	Sept 1993	114	Yes
Coaptite	Nov 2005	3	Yes
Silicone	Dec 2006	–	Yes
Durasphere	Sept 1999	7	Yes
Tegress/Uryx	Dec 2004	201	No

B

Material	Product	Number of reported studies with >50 patients in the last 3 years	Dry or improved (average %)
Collagen	Contigen	15	63
Carbon bead	Durasphere	6	60
Silicone	Macroplastique	8	58
Calcium hydroxyapatite	Coaptite	4	50
Other		3	60
Ethylene vinyl alcohol	Tegress	2	55
Polyacrylamide hydrogel	Bulkamid	3	58

A recent systematic review of randomized trials for noninvasive anti-incontinence procedures included seven randomized controlled trials (RCTs) on a total of 882 women implanted with different injectable bulking agents [35]. The level of evidence was classified as low. Rates of continence and improvement were similar among the different agents in most of the RCTs. Curative effects were shown after intraurethral collagen injection in women with SUI (51.5% were dry during a 24-h pad test) [36]. Transurethral injection of a porcine dermal implant resulted in a negative pad test results (i.e. cure) in 60% of women with urodynamically-proven SUI [37]. Transurethral injection of the bulking agent dextran copolymer resulted in objective cure in 15% of women with stress or mixed incontinence (minor and controlled urge component) in whom previous conservative treatments had failed [15]. Only one RCT reported statistically significant relative benefit. This benefit was seen in 63 women with SUI at 12-month follow-up after

transurethral ultrasonography-guided injections of autologous myoblasts and fibroblasts, compared with conventional endoscopic injections of collagen (relative risk 9.5, 95% CI 2.53–35.63; risk difference 0.81, 95% CI 0.66–0.96) [38]. (This paper has been recently withdrawn for ethical issues.)

Future agents

The most exciting and promising field may be that of tissue engineering. There have been some successes using autologous myoblasts and fibroblasts for urinary incontinence [39], with three-dimensional ultrasound revealing an increase in the size of the urethra and rhabdosphincter from baseline. However, lately these results have been seriously questioned [40].

Conclusions

The role of urethral bulking agents has evolved over the last two decades in parallel to the developing technology of slings. As a result, they are more frequently used in patients with multiple medical comorbidities whose increased surgical risks prevent them from having open surgery. Moreover, once considered a primary treatment, today these agents are best used as an adjunct to a failed sling or other anti-incontinence surgery. The search for a more perfect injectable agent continues as the fields of biomaterials and regenerative medicine now look to better understand SUI.

CHAPTER 142

Single-Incision Slings

Michael J. Kennelly[1] & Erinn Myers[2]

[1]Charlotte Continence Center, McKay Department of Urology, Charlotte, NC, USA

[2]Carolinas Medical Center, Charlotte, NC, USA

Introduction

Stress urinary incontinence (SUI) as defined by the Standardization Sub-Committee of the International Continence Society is the complaint of involuntary leakage of urine with effort, exertion, sneezing, or coughing [1]. It is estimated to affect approximately 25% of women in the USA between the ages of 30 and 60, and surgical therapy has been the mainstay treatment for the last 100 years. Anti-incontinence procedures initially emerged in the form of pubovaginal slings, Burch colposuspensions, and bladder neck suspensions. However, over the last 10 years, minimally invasive synthetic sling procedures have been developed and modified, and now predominate [2–4].

This transition began in the 1990s when Ulmsten and Petros described the integral theory [5]. This theory suggests that a weak pubourethral ligament causes inactivation of the muscle forces that contribute to urethral and bladder neck closure in the regulation of continence. They then demonstrated that a damaged or lax ligament is unable to be tightened effectively with sutures, but could be supported at the mid urethra with an artificial neoligament. Thus, they introduced the first tension-free polypropylene mesh sling to support the mid urethra. It successfully provided continence by reinforcing the pubourethral ligaments with a midurethral tape that was anchored retropubically [5, 6]. The benefits of this new methodology included acceptable cure rates with lower morbidity than found in previous procedures [6].

Since the landmark hypothesis of Ulmsten and Petros, there has been a steady evolution of pubovaginal slings, from retropubic to transobturator, and now single-incision slings. Each subsequent sling has been developed to decrease the unexpected morbidity found with its predecessor, while striving to retain the 82–95% cure rates seen at 1 year with the "gold standard" Burch procedure [2].

Pubovaginal slings

Retropubic polypropylene tape sling

Ulmsten and Petros developed tension-free vaginal tape (TVT), the first minimally invasive retropubic polypropylene tape (RPT) sling procedure performed under local anesthesia for SUI. Their novel procedure begins with injection of local anesthetic abdominally and vaginally along bilateral trocar paths. Through a 1.5-cm vaginal incision, bilateral periurethral dissection is performed to the inferior aspect of the pubic bone. Trocar needles with attached prolene mesh tape, covered by a plastic sheath, are inserted into the vaginal incision and then passed through the urogenital diaphragm, into the retropubic space just deep to the pubic bone and then out through the suprapubic area. Cystoscopy is then routinely performed to rule out any bladder perforations. After the tape is adjusted with a cough test to insure continence, the plastic sheath is removed and incisions are closed [5, 6].

Initial 3-year data demonstrated that this new RPT sling resulted in 86% cure rates and 11% improvement rates [6]. Long-term results observed by Nilsson *et al*. over an 11.5-year period also confirmed subjective cure

rates of 77% and improvement rates of 20% [7]. Randomized controlled trial evidence suggests that TVT has a similar cure rate to colposuspension [8, 9]. Since 1998, several RPT slings have been marketed as either transvaginal or suprapubic needle insertion techniques (Table 142.1). Many of these RPT slings have not yet been adequately tested in observational or comparative trials.

Although the overall efficacy of RPT slings was encouraging, the blind passage of trocar needles into the retropubic space created a new set of potential complications. A review by Atherton *et al*. showed that RPT procedures are associated with a 0.2–1% postoperative urinary retention rate, a 3–4% risk of bladder, urethral or intestinal perforation, and a 1–2.5% risk of major vessel and nerve injury and hematoma in the retropubic space [10]. These complications, although infrequent, lead to further modifications and improvements in minimally invasive urinary incontinence surgery.

Transobturator polypropylene tape sling

In an attempt to avoid rare, but unwanted, complications associated with the retropubic trocar needle passage, Delorme explored the transobturator approach to polypropylene sling placement in 2002. Through an "outside–in" transobturator approach, the trocar needles could be placed at a safe distance from the retropubic blood vessels and viscera, while maintaining proper mid-urethral support [11]. Transobturator tape (TOT) slings involve insertion of trocars around the ishiopubic ramus through the obturator membrane and out through a 1.5-cm midline vaginal incision. After loading the tape onto the trocar, the sling is positioned for mid-urethral support. In 2004, De Leval reported an "inside–out" TOT procedure [12]. In a similar fashion the polypropylene tape was positioned from mid urethra to obturator space, but the trocar was passed from the urethral incision to the groin incision.

Since 2002, several TOT slings have been marketed as either "inside–out" or "outside–in" approaches (Table 142.2). TOT sling cure or improvement rates have been shown to be 90% effective for both these approaches, rates that are comparable to the RPT sling [13–15]. In support of the transobturator method, several studies found the new TOT technique to be equally as efficacious as RPT slings [16–20]. Compared to retropubic slings, the TOT procedure demonstrates minimal risk of bladder perforation and bowel injury; however, there have been reports of subjective groin pain, possibly related to obturator nerve compression or muscle irritation [20]. *De novo* urgency rates appear to be less after a TOT compared to a RPT sling. Botros *et al*. found decreased *de novo* urgency rate with TOT: 8% for TOT versus 33% for transvaginal RPT and 17% for suprapubic RPT [21].

Single incision sling

Soon after the introduction of the TOT slings, engineers began designing the next generation of mid-urethral slings; the single-incision sling (SIS). Building on the RPT and TOT platform of efficacy and ease of use, the SIS was designed to potentially avoid the need for the mesh to transverse any major muscles, reduce risk of organ injury and procedure time, and hopefully achieve a better patient experience (i.e. no external incisions, local anesthesia, minimum postoperative pain, and office-based therapy) [22, 23]. Because of the success of RPT and TOT, the first SIS was designed to be placed

either in the retropubic or transobturator pathway. Early results were mixed and not consistently reproducible due to multiple factors, including fixation technique, surgeon learning curve, and appropriate tensioning techniques [24, 25]. Since their first introduction in 2006, several SISs have emerged. Each SIS is made of type 1 polypropylene, but has a unique sling length, trajectory pathway, delivery device, fixation method, and fixation location (see Table 142.2).

Although the selection of patients for SIS is evolving; most surgeons reserve SIS for SUI patients without prior anti-incontinence surgery. As with RPT and TOT slings, SIS procedures are contraindicated for the following patients: pregnant or planning a pregnancy in the future, or with blood coagulation disorders, compromised immune system, renal insufficiency, and urinary tract obstruction or infection.

Early data are promising that these new SISs can provide successful mid-urethral support with less dissection, shorter procedure time, and less attendant morbidity of leg muscle or obturator nerve adverse events [25–27] (see also Table 143.2, summarizing results).

TVT-Secur System

In 2006, the SIS generation began with the introduction of the Tension-Free Vaginal Tape-Secur™ (Ethicon Women's Health & Urology, Somerville, NJ, USA). TVT-Secur measures 8.0 × 1.1 cm and utilizes the same proprietary macroporous polypropylene fiber used in Ethicon's RPT and TOT slings (Figure 142.1). Besides the shorter length, TVT-Secur's other unique properties include: laser cut mesh, absorbable fixation tips, and multiple placement approaches. Unlike the tanged mesh edges, laser cut mesh edges offer the benefits of consistent width and minimal stretch to facilitate proper placement. The innovative 2-cm absorbable fixation tips made of polyglactin 910 (Vicryl) and poly-p-dioxanone (PDS) provide immediate mechanical fixation which, over roughly 3 months, is replaced by tissue ingrowth. TVT-Secur fixation demonstrates strength over time with initial animal mean pull-out force of 864 g (vs 771 g for the original TVT) that increases to 6509 g at 12 weeks [28]. The versatile design of the TVT-Secur allows placement in either the "U" retropubic trajectory position or

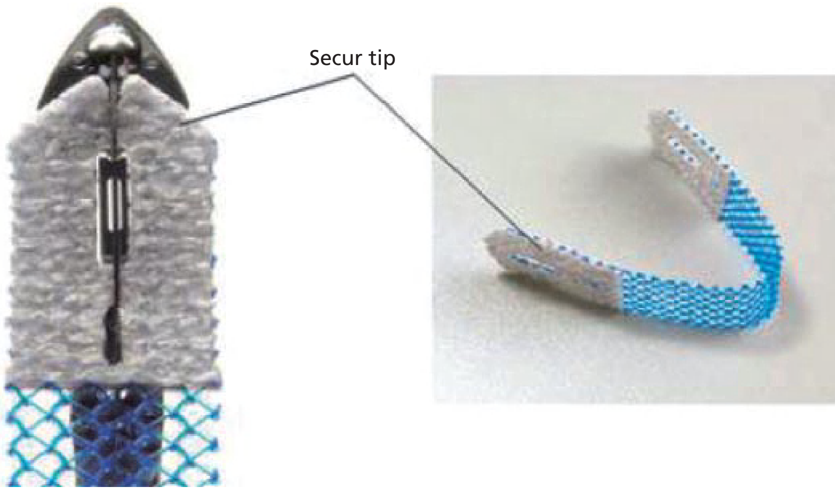

Figure 142.1 TVT Secur System. TVT-Secur laser-cut mesh edges with the 2-cm absorbable fixation tips (reproduced by permission of Ethicon Women's Health & Urology, Somerville, NJ, USA).

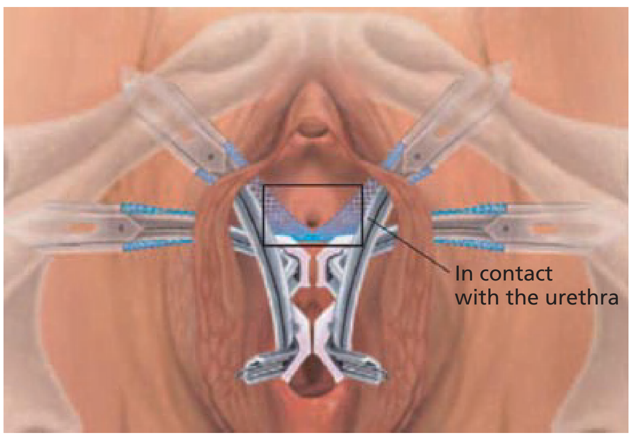

Figure 142.2 TVT-Secur placement. TVT-Secur can be placed in either the "U" retropubic trajectory position or the "hammock" transobturator trajectory position. (reproduced by permission of Ethicon Women's Health & Urology, Somerville, NJ, USA).

the "hammock" transobturator trajectory position [25–27] (Figure 142.2). The "U" configuration mimics the RPT placement with the fixation tips placed into the connective tissue of the urogenital diaphragm against the periostium on the pubic bone. The hammock position imitates the TOT trajectory and the absorbable fixation tips anchor into the muscle complex of obturator internus muscle against the posterior edge of the inferior ischiopubic ramus [29]. As the procedure evolved, it became evident that the fixation tips must remain in contact with the respective bony structures in order to maintain stable long-term fixation. Stabilizing the fixation tips to mobile muscular structures alone proved to provide less than satisfactory results [3].

Procedure

After local infiltration, a 1.5-cm mid-urethral incision is made in the anterior vaginal wall [29]. The vaginal and paraurethral incision should be made slightly larger than with conventional slings in order to accommodate the TVT-Secur device. To avoid dragging paravaginal tissue during insertion, the paraurethral dissection for both the "U" and "hammock" must maintain its initial width.

TVT-Secur "U"

Similar to RPT placement, the dissection is performed to the inferior edge of the pubic bone. The urogenital diaphragm should not be penetrated by the scissors, as this will reduce the holding ability of the fixation tips. Before placing the TVT-Secur, a urethral catheter with guide should be placed to minimize injury to the lower urinary tract by the TVT-S inserter. The TVT-S is placed flat to and in contact with the back of the pubic bone, while being pushed into the dense connective tissue of the urogenital diaphragm and aimed towards the ipsilateral shoulder. Close contact with the pubic bone assures correct placement. The procedure is repeated on the contralateral side.

TVT-Secur "hammock"

Similar to TOT placement, the dissection is performed laterally to the lower edge of the ischiopubic ramus. The obturator internus muscle should not be penetrated by the scissors, as this may reduce the holding ability of the fixation tips. The TVT-S is placed flat to and in contact with the lower edge of the ischiopubic ramus, while

being pushed into the obturator internus muscle. The inserter blade must always stay in contact with the bony surface to achieve long-term fixation. The procedure is repeated on the contralateral side. Proper mesh tension can be achieved with bilateral incremental advancement of the device. Optimal results may not be achieved if the placement is complicated by rotating movements, tearing of the obturator muscle, or placing the device away from the bony pelvis.

Tensioning

Proper device tensioning is essential to successful placement in the “U” or “hammock” position (see Videos 142.1A and 142.1B, respectively). Unlike traditional mid-urethral slings that are pulled into place, the tension of the TVT-Secur single-incision sling will not increase postoperatively. Tensioning options include dynamic cough/Crede stress test or visual assessment, making sure that the sling is flush with the urethra, causing a pillowing effect (filling of the tape pores with suburethral tissue) [29]. Adjustments in tensioning can only be done with the inserters in place and, once the release wires are pulled, it is not possible to reconnect for further adjustments. Cystoscopy may be performed at the physician’s discretion and the incisions are closed according to usual method.

Results

There are several short-term reports of TVT-Secur in the literature; however, very few trials of longer than 1 year have been published. Several of the initial reports of TVT-Secur demonstrated unfavorable outcomes with poor success rates ranging from 67% to 83%, much lower than with the existing traditional RPT and TOT slings [24, 30, 31]. Many authors noted a significant learning curve in the adoption of the TVT-Secur. Improper sling tensioning and not placing the fixation tip against the pubic bone or ischiopubic ramus resulted in device dislocation and immediate or recurring SUI. As experience has evolved and techniques have been refined, long-term studies have demonstrated more consistent results. Procedural modification reported by Neuman *et al*. in their prospective trial of 100 women demonstrated improved success rates and decreased morbidity [29]. By placing the TVT-Secur tape flush to the urethra without space between the tissue and mesh, the continence rates improved from 88.6% in the first 50 patients to 93.5% in the last 50 patients. Tensioning the sling flush with the urethra did not increase the rate of urinary retention or obstruction. When comparing the first 50 patients to the last 50 patients, experience and meticulous attention to dissection and procedural details resulted in fewer adverse events by elimination of vaginal wall penetration with the inserters (8% vs 0%), decreased unintended tape removal by the inserter (10% vs 0%), and fewer tape extrusions (12% vs 8%).

In a prospective multicenter trial evaluating 95 women with urodynamically confirmedSUI, Meshia *et al*. noted a 78% subjective cure rate and 81% objective cure rate (negative cough stress test) with TVT-Secur at 1 year [26]. Although not designed as a comparison trial, there was no difference in success rates for the “U” and “hammock” approaches. Postoperative pain was reported by only one woman. Postoperative complications included voiding difficulty (8%), recurrent urinary tract infection (UTI) (10%), *de novo* urgency incontinence (10%), and dysparunia with mesh protrusion (2%) [32].

Both TVT-Secur approaches appear to have comparable effectiveness. In a randomized comparative trial of 115 women, Kim *et al.* reported no statistical difference in cure rate at 12 months based upon the Sandvik questionnaire: [88.7% (47 of 53) U-type and 87.1% (54 of 62) hammock-type approach, $P = .796$) [33]. Both techniques demonstrated equivalent short operative time (14.8 ± 6.3 min for the U-type approach and 13.4 ± 5.1 min for the hammock-type approach, $P = .114$). Immediate postoperative pain as measured by visual analog scale (VAS) was minimal for each approach (2.2 ± 2.0 for the U-type approach and 2.1 ± 1.8 for the hammock-type approach, $P = .926$). There were no severe complications related to either approach; however, vaginal wall perforation occurred with the hammock-type approach and temporary retention occurred in three patients (two U-type approach and one hammock-type approach).

Overall TVT-Secur in its “U” and “hammock” configurations demonstrates effectiveness in treating SUI with minimal morbidity. There appear to be critical technical points to the procedure that can substantially impact a successful outcome. With experience and attention to detail, TVT-Secur can demonstrate acceptable cure rates compared to RPT and TOT; however, comparative trials and long-term follow-up trials are warranted.

MiniArc sling

One year after the introduction of TVT-Secur, the MiniArc™ (American Medical Systems Inc, Minnetonka, MN, USA) was released in the USA and Europe as the second SIS. The MiniArc consists of an 8.5 cm × 1.1 cm polypropylene sling with integrated self-fixating tips that anchor into the obturator internus muscle through a single vaginal incision (Figure 142.3). MiniArc’s simplified design and approach capitalized on some of the early design criticisms of the TVT-Secur device. Differential design features include the narrow inserter, self-fixation tips, tanged mesh edges, redocking feature, and insertion into the obturator internus muscle. The

Figure 142.3 MiniArc. The MiniArc's 1.1 × 8.5-cm macroporous polypropylene mesh fused to self-fixating tips is placed with a 2.3-mm needle (reproduced by permission of American Medical Systems Inc, Minnetonka, MN, USA).

MiniArc mesh utilizes the same type 1 knitted polypropylene mesh used in American Medical System's RPT and TOT procedures.

The slip-fit mesh-to-needle connection allows easy engagement and disengagement of mesh to needle. Compared to the TVT-Secur, this smooth disengagement feature dramatically lessens the risk of inadvertently moving or loosening the mesh while removing the inserter device. By redocking the needle to the mesh after removal of the inserter, MiniArc's design allows further intraoperative tensioning during placement if desired. With the small 2.3-mm needle diameter, the push-in force required to deliver the MiniArc (2.56 lb) was less than that for the TVT-Secur (4.52 lb) (data on file, American Medical Systems). The polypropylene permanent self-fixation tips were designed to provide short-term holding force that prevents migration during initial tissue ingrowth. Compared to a pelvic floor event at a force of 1.3 lb, cadaver bench testing showed that 5.5 lb of pull-out force is required to remove the MiniArc [34, 35]. Despite these design features, skepticism regarding adoption of MiniArc SIS centers around the initial and long-term fixation strength of the obturator internus muscle and proper tensioning techniques.

Procedure

Similar to other SIS procedures, a 1.5-cm vaginal incision is made at the level of the mid urethra. Bilateral periurethral tissue dissection is performed toward the interior portion of the inferior pubic ramus. The sling/needle assembly is guided along the posterior surface of the ischiopubic ramus in a transobturator trajectory towards the obturator space bilaterally. Once the integrated sling tip is fixed into the obturator internus muscle, the needle is then removed and the procedure repeated on the contralateral side. Upon sling placement, further tension can be delivered by using a redocking feature that provides access to the implanted tip placed on the initial side. The mesh should lie flat against the urethra without any mesh distortion or space between the urethra and sling. Dynamic stress testing (cough stress test/Valsalva test) or visual inspection aids in proper sling tensioning. Cystoscopy may be performed at the surgeon's discretion and the vaginal incision is closed [36, 37] (see Video 142.2).

Results

Several promising results have been reported with the MiniArc SIS. Early clinical reports indicate a shortened procedure time (<10 min), minimal blood loss, quick learning curve, and ability to perform the procedure under local anesthesia [36–38]. There is a paucity of long-term studies; however, all of those to date support the safety of this minimally invasive procedure with efficacy rates that are similar to those for RPT and TOT.

A small study by Palma *et al*. reported an 88% cure rate in 18 patients at 12 months [39]. In 2009, Moore *et al*. reported 1-year retrospective data evaluating the first 61 patients with MiniArc. The procedure time was 7 min (±3.3 min) and estimated blood loss was 27 mL (± 16 mL). Consistent with previous studies, they had an overall cure rate of 91.4% and no adverse complications, including no intraoperative complications, pain, dyspareunia, or sling erosion [38]. The first prospective multicenter international trial was recently published by Kennelly *et al.*, with 157 of the 188 women enrolled available for follow up at 1 year. Based upon procedural data, the MiniArc was minimally invasive with a quick procedure time (mean 11.0 min), minimal estimated blood loss (mean 41.7 mL), short length of hospital stay (mean 9.5 h), and minimal discomfort post procedure (mean pain score 1.3). At 1-year follow-up, 90.6% of patients had a negative cough stress test and 84.5% had a 1-h pad weight test of less than 1 g. No complications such as injury to bowel, bladder, urethra, blood vessels,

abscess or leg neuropathy occurred in this study. Adverse effects are uncommon and likely due to sling placement outside the transobturator space or medial groin muscles [27]. However, Gauruder-Burmester reported that 36.8% of patients developed *de novo* urge incontinence [40]. The placement of self-fixating tips in a tension-free manner is a challenge and depends on factors such as tissue properties, insertion techniques, and tape position/retraction.

Overall, the early MiniArc data regarding efficacy, safety, and patient tolerability is very encouraging. Standardization of tensioning techniques and long-term durability studies will likely foster wider adoption of SIS such as MiniArc.

Solyx

The Solyx™ SIS system (Boston Scientific Corporation, Natick, MA, USA) was introduced in North America in 2009. It consists of a delivery device and a 9-cm mesh assembly with nonabsorbable polypropylene carriers on each end (Figure 142.4). These carrier barbs serve to anchor the sling into the obturator internus muscle while permanent tissue ingrowth occurs over time. The mesh assembly is composed of the same polypropylene mesh used in Boston Scientific's RPT and TOT procedures. The 4-cm central portion of the mesh is heat sealed and detanged to resist deformation and potentially reduce irritation to the anterior urethral wall. The delivery device has a snap-fit on the delivery tip, which is designed to prevent premature carrier slip-off during insertion. In addition, this delivery/carrier attachment allows microadjustability to loosen and tighten the sling prior to releasing the carrier. The tanged lateral mesh portion may allow for minimal loosening and once the carrier is deposited in the obturator internus muscle, it cannot be reconnected onto the delivery device for additional adjustment [25].

Procedure

After local infiltration, a 1.5-cm vaginal incision is made at the level of the mid urethra. Bilateral dissection is performed at a 45° angle toward the inferior pubic ramus, creating a pathway for delivery device placement. The mesh assembly is placed onto the delivery device until it is flush with the end and an audible "click" is heard. The delivery device is inserted and advanced towards the obturator foramen just lateral to the inferior pubic ramus and until the midline mark on the mesh is at the mid urethra. The mesh carrier is released into the surrounding obturator internus muscle tissue by holding the deployment mechanism with one hand and pulling the delivery device handle with the other. The delivery device is removed from the incision and the second mesh assembly is placed on the delivery device and contralateral side placement is repeated. Tensioning options include a cough stress test and visual assessment to ensure the sling is positioned against the urethra (allowing a small enough space to place a small instrument or

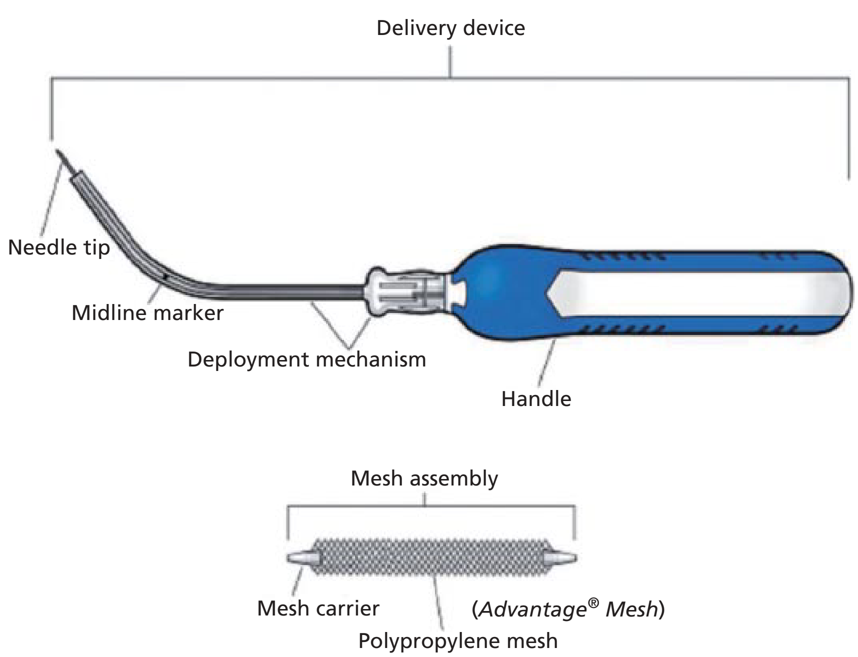

Figure 142.4 Solyx Single Incision Sling System. The 9.0-cm polypropylene sling consists of a mesh assembly with carriers fixed to the ends. The delivery device has a handle, needle tip, and midline marker (reproduced by permission of Boston Scientific Corporation, Natick, MA, USA).

checking that the periurethral tissue "pillows" through the pores in the mesh). With the delivery device still attached to the mesh assembly, modest advances and retreats can be made to tighten or loosen the sling as needed to achieve the desired tension. However, it is important to note that once a carrier is deposited into the tissue, it is not possible to reconnect it for further adjustments [25]. Cystoscopy may be performed at the physician's discretion and the incisions are closed according to the usual method (see Video 142.3).

Results

There is a paucity of peer-reviewed data on Solyx, mainly due to its recent introduction in 2009. In a retrospective review, Serels *et al.* reported their three-center preliminary results for the Solyx SIS system in patients with urethral hypermobility (q-tip > 30°); 59% of patients had concomitant repairs [25]. At a mean follow-up of 6.5 months (range 5–8 months), 95% (60 of 63) were dry both by subjective patient assessment (patient states they are completely dry) and objective physician assessment (negative standardized cough stress test). Only two of 63 patients had transient urinary retention and there were no adverse events of bladder, bowel, vessel or nerve perforations, and no erosions, extrusions, muscle or groin pain. This short-term, prospective analysis provides encouraging data that will need to be confirmed in larger, prospective studies with longer follow-up.

Needleless

The Needleless® System (Neomedic International, Terrasa, Spain) quietly emerged from Europe in 2007. It consists of a 12 cm × 1.4 cm macroporous monofilament polypropylene mesh with a blue midline suture (Figure 142.5). Unique to this device is the lack of inserter needle or anchor system. The patented lateral pocket positioning system provides the initial holding strength in the obturator internus muscle. With only 16% less surface area for tissue ingrowth than a traditional TOT sling, the Needleless sling hopes to offer the same clinical benefits of a TOT sling through a single vaginal incision [41]. Additionally, no sharp introducer needles are required to implant the sling, which enhances patient comfort and is fundamentally attractive for local anesthesia.

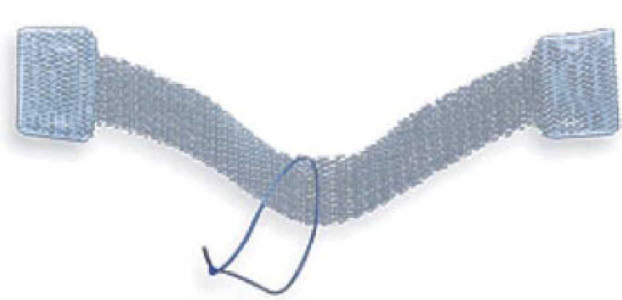

Figure 142.5 Needleless System. The needleless sling has a patented lateral pocket positioning system. The midline blue suture can be removed intraoperatively or left in place for post operative adjustments (reproduced by permission of Neomedic International, Terrasa, Spain).

Procedure

After local infiltration, a 2-cm incision is made at the mid urethra on the anterior vaginal wall. A horizontal submucosal tunnel is dissected to the edge of the ischiopubic ramus. The Needleless sling is prepared by introducing a surgical forceps (i.e. tonsil) in one of the terminal pockets of the sling. The forceps are inserted into the pocket of the sling, and the pocket is folded between the jaws of the forceps. The folded pockets are introduced through the dissected spaces directed at approximately 30° from the midline. The Needleless mesh pockets should be guided to the 10 o'clock and 2 o'clock position respectively, relative to the urethra. The surgical forceps and mesh sling are pushed into the obturator internus muscle to the point that the central sling traction thread is within 1 cm from the urethral midline. Release of the sling is accomplished by opening the forceps, extending the sling pocket positioning/anchoring system, and then carefully closing and removing the forceps. The process is then repeated on the contralateral side. The sling is placed flush with the urethra while counter-traction is used on the central thread to aid in centering the sling. Intraoperative adjustments of the sling can be made by reinserting the forceps into the pockets on either side and advancing the sling further into the muscle. Cystoscopy may be performed at the physician's discretion and the incisions are closed according to the usual method. The traction thread should be cut off, although it may be left in place for a maximum of 48 h, and can be used to loosen the mesh in the case of postoperative urinary retention [41] (see Video 142.4).

Results

Despite being developed in 2007, scant peer-reviewed literature is available for the Needleless sling. Navazo *et al.* reported their preliminary experience with their first 120 patients undergoing the Needleless procedure [41]. All patients had urodynamically confirmed SUI and 83% (100 of 120) had concomitant repairs. The mean procedure time was 10 min (range 5–1 5 min). Based upon a negative cough test, 100 patients (84%) were objectively cured, 10 (8%) improved their incontinence, and 10 (8%) were considered failures. This series did not

report any cases of inguinal pain, hemorrhage, hematoma, vascular or visceral damage; however, there was one sling extrusion managed successfully with estrogen cream.

Over the years, several Needleless abstracts have been presented at various international society meetings. Beya *et al*. reported 1-year follow-up in a prospective multicenter study of 78 patients with SUI [42]. Mean operative time was 7 min (range 4–20 min) and hospital stay was 8 h (range 4–24 h). Based upon objective and subjective measures, 69 patients (88%) achieved cure of stress incontinence, four (5%) improved, and six (7%) failed. There were no immediate complications; however, four partial erosions (5%) were successfully managed with local estrogen therapy. Two patients had *de novo* urge incontinence and three had urge urinary incontinence managed with antimuscarinic agents.

Another Spanish multicenter trial involving 230 females with SUI was presented in 2008 [43]. All patients had urethral hypermobility and patients with neurogenic incontinence or intrinsic sphincter deficiency were excluded. The mean age was 51 years (41–70 years) and mean operative time 9 min (range 7–14 min). After a mean follow-up period of 12 month, 198 patients (86%) were objectively cured of SUI, 14 (6%) improved, and 18 (8%) failed based upon cough stress test. Complications included five temporary retentions, two nonintervention hematomas, and two partial sling extrusions treated with local estrogen therapy.

Initial reports of the Needleless procedure are encouraging. Further multicenter studies with longer follow-up need to be published to confirm the long-term effectiveness of this technique.

Ajust

The Ajust™ Adjustable Single-Incision Sling System (CR Bard Inc, Murray Hill, NJ, USA) was introduced in Europe in 2008 and North America in 2009. It was designed to offer all the benefits of a TOT sling procedure through just one vaginal incision. The Ajust sling system includes: a fully adjustable sling with self-fixating polypropylene anchors; an introducer designed to place the sling in the obturator membrane; and a flexible stylet used to lock the sling after adjustment (Figure 142.6). Unlike other SISs, the Ajust sling is placed through the obturator membrane, mimicking a traditional TOT sling placement. This new sling utilizes the obturator membrane fixation through a single-incision approach versus the three-incision pull-through approach of traditional TOT slings. For most single-incision slings, adjustment is dependent upon manipulating the introducer/needle mechanism and postinsertion adjustment is not feasible. The Ajust polypropylene mesh sling features two anchors, one fixed and one adjustable, and is constructed with a suburethral section, as well as a tubular adjustment mesh that slides in either direction through the anchor. These mesh design features allow bidirectional independent adjustment (tightening and loosening) of the sling mesh relative to the anchors without visual obstruction from the introducer in the surgical field. After optimal sling tension setting, the flexible stylet is utilized to lock the sling into place.

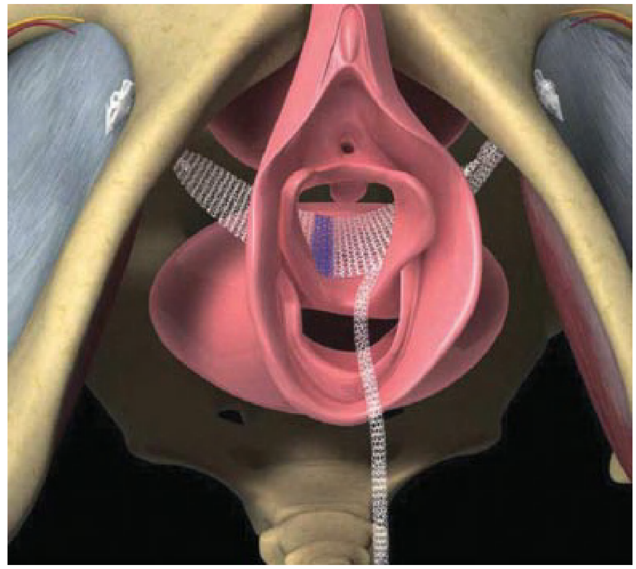

Figure 142.6 Ajust Adjustable Single-Incision Sling. The Ajust is placed through the obturator membrane with self-fixating anchors. Postinsertion adjustments can be made by loosening or tightening the mesh relative to the fixed anchors (reproduced by permission of CR Bard Inc, Murray Hill, NJ, USA).

Procedure

After local infiltration, a 1.5-cm incision is made at the mid-urethral level on the anterior vaginal wall, and a horizontal tunnel is created up to the edge of the ischiopubic ramus. The device is then inserted horizontally towards the cephalad margin of the ischiopubic ramus, and pushed straight into the obturator internus muscle. Once the fixed anchor passes the ischiopubic ramus, the surgeon must pause from the original push while pivoting the introducer handle past the midline, and then resume a second straight push maneuver to place the anchor completely through the obturator muscle and membrane. The midline indicator must be deviated past the midline toward the fixed anchor side to confirm proper depth of placement. The fixed anchor is then released and traction is applied to the suburethral portion of the sling to confirm proper anchor engagement. The adjustable anchor is then loaded into the

introducer and the steps are repeated on the opposite side. Once the adjustable anchor is correctly placed, the adjustment tab and tubular mesh is then pulled until the surgeon achieves the desired "set-point" of the suburethral sling. Once optimal setting has been achieved, the flexible stylet is used to advance the sling lock into the adjustable anchor, locking it in place. The system is designed to permit post-anchor insertion bi-directional tension adjustability (loosening and tightening) after the sling implantation without further insertion of the introducer. Cystoscopy may be performed at the physician's discretion and the vaginal incision is closed according to the usual method (see Video 142.4).

Results

There are no peer-reviewed reports of the experience of Ajust to date; however, several abstracts have been presented at international meetings. Naumann *et al.* reported their four-center prospective observational study on their first 30 patients of whom nine had previously failed SUI therapies in 2009 [44]. Nearly 50% of the surgeries were done under local anesthesia and no concomitant prolapse surgery was performed. All procedures were done in under 15 min without any intra- or post-operative complications. At a mean follow-up of 3 months, all 30 patients were dry based upon clinical examination, although one patient experienced mild urgency. There were no cases of dysparunia or other pain at 3 months based upon VAS scores.

At the International Continence Society meeting in 2010, Naumann *et al.* presented the multicenter 1-year follow-up on their first 52 patients [45]. All but one of the procedures were completed in less than 30 min and 98% of the Ajust implants were successful (one case converted to a TOT), but one case was removed after 2 weeks due to dislocation. At 1-year follow-up, 45 patients demonstrated total restoration (86.5%) of their continence, one demonstrated improvement (1.9%), and five failed (9.6%) based upon a standardized stress test. There were no cases of dysparunia or other pain at 12 months based upon VAS scores.

At the same meeting, Lucente *et al.* reported on a single French center prospective observational study in 43 patients [46]. Forty patients received local anesthesia and were managed on an outpatient basis, whereas three patients had general anesthesia and were hospitalized for 24 h. The mean operative time was 14.9 min (range 10–15 min). One patient had a postoperative vaginal bleed and one had urinary retention successfully managed with 1-day catheter drainage. At a mean follow-up of 8.4 months (range 4–14 months), 91% (39 of 43) wore no pads, had a negative cough stress test, and were fully satisfied based on validated patient global impression of improvement scale.

Overall, the various preliminary reports of the Ajust sling have demonstrated its short-term effectiveness in treating genuineSUI, with limited and mild complications or adverse events. The anchoring into the obturator membrane with bi-directional adjustability appears to have very good initial subjective and objective success rates. Further prospective studies with longer follow-up are needed to prove the sustained durability and efficacy.

Conclusions

SUI is debilitating and treatable with surgical interventions. Excellent success rates have been reported with both the RPT and TOT slings; however, both approaches require blind passage of trocars that risks visceral and vascular damage. Since 2006, SISs have been used in an attempt to decrease the morbidity associated with the minimally invasive approach. However, these procedures must be approached with caution and providers must understand that minimally invasive slings are not simpler, but require much attention and detailed dissection. It is anticipated that decreased complications, high continence rates, and ease of application under local anesthesia may eventually allow SISs to become an office procedure. The encouraging initial results from SISs must be demonstrated over the long term, and comparative trials to the current gold standard RPT and TOT slings are needed to solidify SISs as a first-line treatment option for women with SUI.

CHAPTER 143

Mid-Urethral Slings for the Treatment of Female Stress Urinary Incontinence

Eva Fong, Sagar Shah & Victor Nitti
New York University School of Medicine, New York, NY, USA

Introduction

Stress urinary incontinence (SUI) is a condition that affects the psychosocial welfare, interpersonal relationships, quality of life, productivity, and general health of afflicted women. Its prevalence has been reported to range from 14% to 46% in women older than 18 years of age [1–3]. The prevalence of SUI in women peaks at middle age and then declines slightly in favor of mixed and urge urinary incontinence thereafter [1, 2, 4, 5]. Despite this significant prevalence, due to the invasive nature and associated prolonged recovery of surgical options offered in the past, many women did not undergo treatment.

Since Ulmsten described the tension-free vaginal tape (TVT; Ethicon, Somerville, NJ, USA) procedure in 1995, "An ambulatory surgical procedure under local anesthesia for treatment of female urinary incontinence." mid-urethral synthetic slings (MUSS) have grown in acceptance and popularity to gain a leading position in SUI surgery [6]. They have become the new gold standard for the surgical treatment of female SUI, not only because of their simplicity for both the surgeon and the patient, but also because of excellent surgical outcomes and low morbidity. There are numerous studies, both randomized controlled trials (RCTs) and well-designed prospective studies, which provide a large amount of level 1 and 2 evidence that supports the concept of a sling placed at the level of the mid urethra. In addition, there is increasing evidence regarding how different approaches for placing a MUSS (retropubic and transobturator) can be applied to specific patient groups. This evidence base will be reviewed to help resolve clinical dilemmas concerning which type of sling to use in specific situations.

In this chapter we will also describe the anatomic basis and techniques of MUSS, examine their indications and outcomes, describe some of the newer "less invasive" techniques, and discuss the management of complications that can occur after MUSS placement.

Mechanism of action

The theoretical basis for the original TVT procedure was the "integral theory of female urinary continence," based on a series of anatomic studies of the female urethral closure mechanism performed by Petros and Ulmsten in the 1990s [7]. An important alternate theory, the "hammock" theory, was advanced by DeLancey in 1994 [8]. Both of these theories strive to explain how urethral pressure can be maintained above vesical pressure during increased intra-abdominal pressure. In the integral theory this is explained by opposing forces; the pelvic floor muscles act through their vaginal attachments to stretch the vaginal hammock against the pubourethral ligaments, shutting the urethra off from behind. Weakness in the pubourethral ligaments would lead to similar forces opening the urethra. The more practical "hammock theory" proposes that both urethral support and constriction are important. In this model, the support is provided by the layers outside the urethra on which it rests: the anterior vaginal wall, the endopelvic fascia between the arcus tendineus facia pelvic on each side, and the pelvic floor muscles. With increased

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

intra-abdominal pressure, the urethra remains shut against this backboard, as long as it is intact. When the backboard is not intact, urethral hypermobility and/or SUI may result. It has been shown by ultrasound studies that placement of a sling at the mid urethra causes a dynamic kinking of the urethra with stress and thus can cure stress incontinence without affecting position or urethral mobility [9].

Anatomic approaches

Retropubic MUSS (Figure 143.1)

The original TVT procedure placed a polypropylene sling at the level of the mid urethra via a "bottom–top" approach. This involved the passage of a trocar from a mid-urethral vaginal incision through the endopelvic fascia and the retropubic space to a suprapubic exit point. The "top–bottom" technique was developed by Deval *et al.* [10] with the introduction of the suprapubic arc system (SPARC; American Medical Systems Inc, Minnetonka, MN, USA) sling. This technique involves passage of the trocar from a suprapubic incision (lateral to the midline) to a subepithelial vaginal dissection. Subsequently, there have been a number of different modifications of the "bottom–top" and "top–bottom" approaches using minor modifications of sling material and surgical instrumentation.

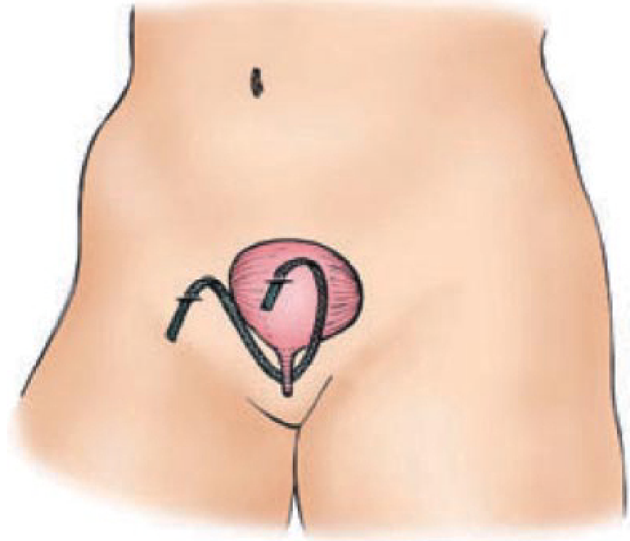

Figure 143.1 Tension-free vaginal tape (TVT) *in situ* (reproduced from Bullock, T.L., Ghoniem, G., Klutke, C.G., Staskin, D.R. Advances in female stress urinary incontinence: mid-urethral slings *BJU Int* 2006;98 (Suppl 1):32–40; discussion 41–42, with permission).

Transobturator MUSS (Figure 143.2)

The transobturator approach was introduced by Delorme *et al.* to avoid trocar passage in the retropubic space/pelvis, which addressed concerns over bladder, bowel, and major vessel injury and voiding dysfunction following TVT [11]. In this approach, vaginal dissection is as per the retropubic approach. Both transobturator approaches involve trocar passage between the vaginal incision, through the obturator membrane and obturator internus muscle to a groin incision below the adductor muscle insertion. The original transobturator tape (TOT) operation was described as an "outside–in" technique, with the tape being passed from the thigh into the vaginal incision (Uratape; Porges-Mentor, Le Plessis, Robinson, France). In 2003, de Leval further modified the technique: in this "inside–out," approach, a vaginal incision is made through the obturator foramen and out of the inner thigh [TVT-Obturator (TVT-O); Ethicon, Somerville, NJ, USA] [12].

Figure 143.2 Transobturator tape (TOT) *in situ* (reproduced from Bullock, T.L., Ghoniem, G., Klutke, C.G., Staskin, D.R. Advances in female stress urinary incontinence: mid-urethral slings *BJU Int* 2006;98 (Suppl 1):32–40; discussion 41–42, with permission).

Types of mesh

A number of different synthetic materials have been used as slings over the past decades. Both monofilament and multifilament materials have been tried. The ideal sling material should be inert, nonallergic, and relatively resistant to inflammation and infection. Synthetic meshes are divided into four groups: Type 1, macroporous, monofilament; Type 2, microporous; Type 3, macroporous, multifilament; and Type 4, submicronic, coated biomaterials with pore sizes of less than 1 μm. Since the introduction of the MUSS, it has become clear that slings made from Type 1 mesh are superior to other slings, predominately because they are relatively resistant to infection and inflammation.

Table 143.1 Steps of the tension-free vaginal tape (TVT) procedure (modified from Ulmsten [16]).

1.	Bladder is emptied at the outset of surgery. This allows passage of trocars around an empty bladder, reducing the chance of bladder perforation
2.	Local anesthetic can be injected in the path of trocar placement and just below the vaginal epithelium to facilitate dissection in the correct anatomic plane beneath the epithelium but above the periurethral fascia
3.	A 1.5-cm midline longitudinal vaginal incision is made, beginning approximately 0.5 cm proximal to the external urethral meatus, but not extending to the bladder neck to avoid bladder neck obstruction with the sling
4.	Subepithelial plane is dissected laterally from the midline vaginal incision to the endopelvic fascia, minimizing disruption of structures through which the sling will pass. A space large enough to insert an index finger to palpate the endopelvic fascia is made
5.	A stainless steel catheter guide is placed within the Foley catheter, allowing identification of the urethra and bladder neck during trocar passage. This may also help to position the bladder neck for trocar passage
6.	Trocar (with attached TVT) is placed within the previously dissected subepithelial plane. The endopelvic fascia is perforated and the trocar is guided into and through the retropubic space. Close contact with the back of the pubic bone (and avoidance of lateral deviation) is necessary to avoid vascular or visceral injury
7.	A small suprapubic incision is made bilaterally just above the pubic bone, about 2 cm lateral to the symphysis pubis, and the trocars exit here
8.	Cystoscopy is preformed with a full bladder to make certain that there is no bladder or urethral injury. If there is an injury, the trocar is removed and repositioned
9.	Trocar and attached tape are pulled up and the TVT is placed at the level of the mid urethra without tension a Hagar dilator, clamp or pair of scissors beneath the sling can be used to prevent overtightening)
10.	In the awake patient, a cough test may be preformed to help adjust tension
11.	Casing of the tape is removed
12.	Vaginal wall is closed
13.	Excess tape is excised at the level of the skin incisions on both sides and these are closed
14.	(In most cases a catheter is not necessary postoperatively)

Slack *et al.* showed in an *in vivo* study that Type 1 mesh had an early and sustained filling with fibrous connective tissue and capillaries, showing that macroporous meshes promote tissue host ingrowth with resultant integration, allowing anchoring of the mesh within the tissue [13]. The provoked inflammatory response decreases markedly with time, thus reducing the risk of infection. Both type 2 and 3 meshes had a much more marked inflammatory response without as much fibrous ingrowth. ObTape in particular had barely any fibrous tissue or capillary ingrowth. These findings are in concordance with several other studies that support Type 1 mesh as having optimal qualities for use in suburethral slings. [13] The largest trial comparing monofilament and multifilament slings was published by Meschia *et al*. of 190 patients randomized to TVT or intravaginal slingplasty (IVS) [14]. At 24-month follow-up only vaginal erosion was significantly more common after IVS than TVT. In 2005, Domingo *et al.* reported a 13.8% extrusion rate for the ObTape [15]. Based on the above animal and clinical studies, all commercially available mid-urethral slings are now made from Type I, non-coated mesh (see Table 142.1).

Surgical technique

Retropubic MUSS

The original TVT technique and the SPARC techniques are described, recognizing that other slings are a variation on these techniques. Ulmsten's original technique described the use of intravenous sedation to allow for an intraoperative cough test and adjustment of sling tension [6]. This is not always employed now, so that general or regional anesthesia or sedation may be used.

The crucial steps of the TVT procedure are listed in Table 143.1 [16].

The SPARC technique is very similar except that the trocars are placed from the suprapubic incision downwards [10]. The vaginal incision is performed as for the TVT. After bilateral paraurethral dissection of the vaginal wall, two small horizontal suprapubic incisions were made, no more than 2 cm lateral to the midline, for needle entry. The needle is grasped with one hand on the handle and the other hand on the curved portion of the needle, near the abdominal incision, to control the direction of the needle tip. Then, the needle is passed through one of the suprapubic incisions, down the posterior side of the pubic bone towards the vaginal incision. The needle tip should remain in contact with the posterior pubic bone until it has passed through the endopelvic fascia. Using the index finger of the other hand, the surgeon locates the tip of the needle, then guides it through the vaginal incision. With the first needle in place, the surgeon inserts the second needle on the contralateral side, in the same way [10]. Cystoscopy is preformed to check for a bladder or urethral injury. The sling is attached to the end of each trocar and pulled up through the suprapubic incision. The sling is tensioned similarly to the TVT.

Transobturator MUSS

As with retropubic MUSS, a number of similar devices have been introduced, both outside–in [11] and inside-out [12]. Currently available commercial slings and their approaches are listed in Table 142.1. Anatomic studies have shown that with this method the synthetic sling is entirely outside the pelvis (and also retropubic space), within the foremost extension of the ischiorectal fossa [17, 18]. For "outside–in placement," the vaginal dissection is performed as per the original TVT operation. A puncture incision is made 15 mm lateral to the ischiopubic ramus on a horizontal line level with the clitoris. The trocar is held in the same hand as the side on which the operator is working. It is held vertically with the handle downwards; it is then introduced through the skin incision and crosses the obturator membrane. As the membrane is crossed, a specific resistance is felt and the handle is rotated to allow palpation of the tip on the finger within the vaginal fornix [19].

The "inside–out" technique differs in that a small introducer is placed beneath the vaginal epithelium and perforates the obturator membrane. The trocar is then introduced into its grooved surface and rotated 90° toward the thigh, exiting a skin incision made at the level of the clitoris and below the adductor longus tendon.

For both techniques it is important that the trocar (and tape) exit/enter the obturator foramen at its superior–medial border, away from the obturator vessels. TOTs tend to tighten when the casing is removed, therefore extra care needs to be taken to avoid this. Although the risk of bladder and urethral perforation are lower for transobturator versus retropubic sling placement, it is not zero. Therefore, we recommend performing cystoscopy after all transobturator sling placements to insure that the bladder and urethra have not been injured.

Results

Comparisons of outcomes in incontinence surgery are hampered by variations in definition of success. Definitions of cure may be subjective where the patient reports absence of stress incontinence, preferably by a validated questionnaire or instrument, or objective where the absence of incontinence is proven by a negative cough or pad test. In addition, various levels of subjective and objective improvement may constitute success depending upon the study protocols.

Long- and intermediate-term data are now available from a number of MUSS trials that provide level 2 evidence for durability of treatment. Nilson *et al.* have published long-term data for the original TVT procedure [20]. Their most recent publication provides level 2 evidence with a mean follow-up of 11.5 years for 69 of the 91 (77%) patients in their original series. Objective cure, defined in this group as negative cough test on examination or a 24-h pad test of less than 8 g, was found in 90% of women. Subjectively, 77% considered themselves cured based on the Patient Global Impression of Improvement (PGI-I). Intermediate term data are now available for the transobturator technique. Liapis *et al.* recently reported follow-up at 4 years for TVT-O with a cure rate of 82.4% in 74 patients, and Waltergny *et al.* reported 3-year follow-up of the original TOT series described by de Leval [12] with a cure rate of 88.4% [21, 22].

Perhaps the best way to describe the results of MUSS is to look at the level 1 and 2 evidence of various randomized controlled and comparator trials. These trials compare MUSS to other surgical procedures. Most of these studies contain "index" patients who are patients with SUI only and evidence of urethral hypermobility. We will also discuss the use of slings in patients other than these patients and present the evidence regarding their success in these groups.

There have been several high-quality reviews of the literature on synthetic slings. A recent Cochrane review by Ogah *et al*. found 62 randomized trials including synthetic slings [23]. These included comparisons between synthetic slings and traditional sling operations or colposuspension, retropubic "top-down" versus "bottom-up" approaches, transobturator "outside–in" versus "inside–out", and retropubic versus transobturator route. Prior to this Novara *et al*. had reviewed the complication rates in a meta-analysis published in 2008 [24].

MUSS versus other surgical procedures for stress urinary incontinence

Initial level 1 evidence for TVT comes from the Ward and Hilton trial, a multicenter randomized controlled trial of TVT versus Burch colposuspension [25]. In the original publication, the authors showed that TVT and colposuspension have equivalent efficacy (based on very strict criteria, with "lost to follow-up" considered a failure), with 51% cure for TVT versus 63% for Burch colposuspension. The authors also reported 5-year follow-up data on 117 patients [26]. For the primary efficacy variable of a negative 1-h stress pad test, there was no difference in success (81% vs 90%). Furthermore, secondary variables of cure of stress leakage (63% vs 70%), and satisfied or very satisfied (91% vs 90%) showed no difference. Hospital stay was significantly shorter for the sling group. There was no difference in the chance of reoperation. However, patients who had colposuspension were more likely to require prolapse surgery (7.5% vs 1.8%). The authors did note that identifying true durability of cure was somewhat hampered by loss to follow-up across both groups, as only 119 of

the original 377 patients had full 5-year subjective and objective datasets. A sub-analysis of the trial by Manca *et al.* showed that TVT was more cost-effective than Burch colposuspension, with greater gains in quality-of-life years gained [27].

The Cochrane review found nine randomized trials comparing MUSS to traditional slings. MUSS had a shorter operative time (35 vs 87 min) and shorter hospital stays [relative risk (RR) = 0.5]. Different quality-of-life (QoL) measures were used in each study, but all showed similar outcomes for traditional versus synthetic slings [23].

For open colposuspension versus slings, nine randomized trials were included. Objective cure rates at 12 months (n = 729) were 79% for synthetic slings versus 82% for colposuspension. For laparoscopic colposuspension versus slings, the combined results of six trials showed no significant difference in patient-reported outcomes within 12 months; 80% for slings versus 74% for colposuspension. By clinician assessment there was a significant difference in favor of synthetic slings (89% vs 78%) [23].

Comparator trials for retropubic MUSS

The Cochrane review found three trials reporting on patient-reported cure (defined as absence of leakage on stress) for retropubic MUSS; these showed a significant difference in favor of the "bottom–top" versus "top–bottom" approach at 12 months (85% vs 77%) [23]. The combined analysis of objective cure rate (by pad test or stress test) also favored the bottom–top, but by a smaller margin (92% vs 87%).

Comparator trials for transobturator MUSS

There are four randomized studies which directly compare "outside–in" to "inside–out" transobturator slings [28–31] These demonstrate equivalent cure rates over the short and medium term; objective cure rates range from 83% to 98% for outside–in, and from 87% to 90% for inside–out. By subjective measures, most often the PGI-I, cure rates for inside–out ranged from 83% to 90.7%, and for outside–in from 77% to 88.7%. Similarly in Latthe *et al.*'s meta-analysis of transobturator slings, indirect comparison of TVT-O and TOT showed equivalent cure rates [32].

Rretropubic versus transobturator approaches

Two meta-analyses have compared retropubic with transobturator slings. In 2003, Sung *et al.* identified 18 eligible studies, both randomized (492 patients) and cohort (2099 patients) [33]. They were unable to assess a pooled estimate for objective cure as only one randomized study reported this and the four cohort studies used different definitions for reporting. The cohort studies showed a 12.3% failure rate for the transobturator and a 13.7% failure rate for the retropubic approach. The pooled odds ratio (OR) for subjective failure in five of six randomized studies reporting this, was 0.85 (95% CI 0.38–1.92), and the failure rate in the transobturator group was 5.7% versus 7.8% in the retropubic group. These results did not change when patients only with greater than 1-year follow-up were analyzed. Results from the pooled subjective outcomes from cohort studies were similar with an OR of 0.73. This led these authors to conclude that there was no statistically significant difference in subjective outcomes between the two approaches. They do caution, however, that this does not mean that there is no difference, simply that the data available to them did not show a difference.

Long *et al*. have compared the approaches in a meta-analysis of the more recent literature, January 2008 to March 2009 [34]. They identified 11 studies, six RCTs and five cohort studies. Again, reported outcomes differed between studies; three RCTs reported on objective cure, one on subjective cure, and two on changes in QoL or reoperation rate. The short-term cure rate was borderline inferior for the TOT group (OR 0.62, 95% CI 0.37–1.00), nearly reaching statistical significance (P = .05). The authors commented that this result could be due to inclusion of Schierlitz *et al*.'s study of women with intrinsic sphincter deficiency (ISD) (see below) [35].

In the recent Cochrane review, Ogah *et al*. reviewed 24 trials that compared the retropubic and transobturator approaches of MUSS placement [23]. Subjective cure was reported in 10 trials with a total of 1281 participants, and showed no statistically significant difference between routes. In 17 trials with 2434 participants, women were slightly less likely to be objectively cured with the transobturator route (84%) compared with the retropubic route (88%); the RR for objective cure was 0.96 at 12 months (95% CI 0.93–0.99), although there was no significant difference in subjective cure rates (83% in both groups; RR 1.01, 95% CI 0.96–1.05).

Sung *et al*. in their review of six RCTs and 11 cohort studies in 2591 women showed no difference in subjective failure rate between the two routes; 5.7% for transobturator versus 7.8% for retropubic in the RCTs, and 15.4% for transobturator versus 12.8% for retropubic in the cohort studies. They did, however, note a lower risk of complications and *de novo* irritative voiding symptoms for the transobturator group. They concluded that it would take an RCT of 30 000 women to demonstrate superiority of one approach over the other. Similarly, Latthe *et al.* found a total of 14 trials comparing either TVT-O or TOT to TVT, and showed no difference in subjective cure rate [36].

Based on these studies we believe that for the index patient, transobturator and retropubic MUSS offer similar efficacy, with perhaps a slight advantage for the transobturator approach with respect to intraoperative and long-term complications.

Results for MUSS in special populations

Mixed incontinence

With any SUI operation in the patient with mixed symptoms, there are always concerns about lower cure rates for the stress component, and persistent urgency and urgency incontinence for the overactive bladder component. With respect to cure of the stress SUI, studies on MUSS have shown favorable results. Duckett *et al*. studied 51 of 344 women undergoing TVT who had both detrusor overactivity (DO) and urodynamic SUI [37]. They found that SUI was cured in 92%, with an objective cure of DO in 47%, and resolution of urgency incontinence in about 60%. Similarly, Nilsson's update of the original series in 2001 included 59 (of 161) patients with mixed urinary incontinence (MUI), but no DO [38]. At a mean follow-up of 16.7 months, the cure rate for MUI patients of 81.4% was not statistically different from that for patients with pure stress incontinence (88%).

Two studies by Paick *et al*. reported on patients with MUI [39, 40]. The first, which reported on 73 of 274 patients with MUI who underwent TVT with at least 6-month follow-up, showed that the MUI group had the same cure rate for SUI as the SUI-only group. They also found that 16.4% of the MUI group had persistent urgency incontinence, so that overall urinary continence cure was lower for the MUI than the SUI group, but still quite favorable (78.1% vs 95.5%) [39]. In their second study, they reported on 144 women with MUI. Cure rates for SUI only showed no statistical difference for TVT, SPARC, and TOT at 95.8%, 909.9%, and 94%, respectively [40]. Results were also not statistically different for total cure (incorporating urge incontinence) with TVT, SPARC, and TOT showing rates of 81.9%, 77.3%, and 78%, respectively. There were no risk factors for cure of SUI but DO on urodynamic study was a risk factor for treatment failure of urinary urge incontinence. There was one notable difference between preoperative characteristics between the groups: the TOT patients had significantly less severe incontinence than both the SPARC and TVT patients.

To further stratify patients with MUI, a study of 1113 patients compared those who presented with predominant stress, equal stress and urgency, and predominant urgency incontinence [41]. Preoperative urodynamic parameters, including DO, were not reported in this study. Overall outcomes in these MUI populations were good; 87.3% and 82.7% were stress test dry at 7 and 38 months of follow-up, respectively. These authors had strict standards for cure; for subjective cure this was both being very satisfied and having stress and urgency indices of 2 or less on standardized questionnaires, while objective cure had to include a negative stress test (pad test <10 g). There was no difference in rates of "stress test dry" at 7 and 38 months between the groups, though there was a trend to lower cure rates for urgency-predominant incontinence at 38 months (75.3% compared to 84.7% for stress-predominant incontinence). There were, however, statistically significant differences between objective and subjective cure, pad test dry, and patient satisfaction for predominant stress versus predominant urgency patients at 7 and 38 months, with urgency-predominant incontinent patients faring worst in all parameters. Also, these authors found that rates of urgency incontinence compared with preoperative status deteriorated between 7 and 38 months. Holmgren *et al.* also showed deterioration over time in 2–8-year follow-up [41]. Women with pure stress incontinence maintained a cure rate of 82% to 8 years, whereas women with MUI had a lower cure rate: 60% to 4 years with a further decline to 30% in patients at 4–8 years after surgery.

Overall these results suggest that women with MUI can do well with sling surgery with respect to SUI; however, they should be carefully counseled that urge symptoms can persist with significant impact on patient satisfaction. We believe that women should not be excluded for MUSS surgery based on the presence of urgency incontinence or symptoms.

Obesity

There are no prospective randomized studies that have examined obesity as an independent variable across different surgical procedures to treat SUI. Six published studies that have shown that there is no decrease in cure after TVT, and one study has shown a difference [42, 43]. Most recently, a retrospective study by Killingsworth *et al*. reviewed outcomes in TVT at 1 year by PGI-I, urogenital distress inventory (UDI-6), and incontinence impact questionnaire (IIQ-7), finding no differences in satisfaction, improvement in QoL, and complications between three groups of normal [<body mass index (BMI) 25], overweight (25–30), and obese (>30) women [42]. A single study by Hellberg *et al*., where 970 women were telephone surveyed post TVT (mean follow-up 5.6 years), showed significant differences in cure from 81.2% in those with a BMI less than 25 to 52.1% cure in those with a BMI greater than 35 [43]. However, this study did not control for preoperative symptom severity and did not use a standardized questionnaire. There are no data specifically reporting outcomes for transobturator slings in obese women.

Elderly

The affect of age on outcomes of MUSS is relatively undefined. There are a number of confounding variables, such as a higher rate of DO and ISD in the elderly. Also, the definition of elderly varies between studies. At best we can say that there is conflicting evidence regarding age and its impact on MUSS outcomes. Liapis *et al.* reported a cure rate of 76.4% in 55 patients with a mean age of 75.4 years [44]. Pugsley *et al.* reported a cure rate of 77% for women over 70 years compared to 92% for those younger than 70 years undergoing TVT and colposuspension; however, there was considerable disparity in number with only 22 in the older group versus 100 in the younger Group [45]. Sevestre *et al.* demonstrated a cure rate of 67% in 76 patients with a mean age of 76 [46]. Hellberg *et al.* also analyzed their results for TVT in the "very old" versus other patients, finding a reduced cure rate of 56% for those older than 75 years compared to 80% for those younger than 75 years [43]. Conversely, Gordon *et al.* demonstrated similar cure rates between younger (mean age 57.8 years, n = 208) and older (mean age 74.9 years, n = 123) patients undergoing TVT at 12 months, with absence of persistent stress incontinence in 6% and 7%, respectively. A significant difference between these groups was the frequency of concomitant prolapse repair (81% of older women vs 67% of younger women) [47]. Two other studies have also reported equivalence between these groups for TVT [48, 49]. Campeau *et al.* compared immediate to 6-month delayed placement of TVT in 69 women aged over 70 years. At 6 months, the sling group had improved QoL and patient satisfaction compared to the delayed group [50].

Perioperative morbidity and complications are also a consideration in older patients, with several authors showing higher rates in elderly patients. Gordon *et al.*'s study showed the risk of *de novo* urge was 18% at 1 year in older patients versus 4% in younger patients [47]. Also, in the elderly group there were two cases of pulmonary embolism, two of cardiac arrhythmia, one of severe pneumonia, and one of deep vein thrombosis, compared with none of these in the younger group other than one cardiac arrhythmia. Pugsley *et al.* showed that there was higher rates of patients requiring intermittent self-catheterization, UTI, and division of tape (OR = 29). Campeau *et al.* reported significant perioperative complications: bladder perforation (22.6%), urinary retention (12.9%), UTI (3.2%), and *de novo* urgency (3.2%) [50]. At present there are no studies that report on transobturator slings specifically in an elderly population.

Recurrent stress urinary incontinence

There are several studies that specifically address surgery for recurrent stress incontinence after failed transobturator or retropubic slings or mini-slings. Liapis *et al.* recently published a series of 31 such patients [51]. They found the overall cure rate when placing a TVT in patients with recurrent SUI was 74%. However, it was highest (>80%) in those who had urethral hypermobility and no ISD. Success was reduced but satisfactory (63%) with low urethral mobility (<30°) and no ISD, and was low (40%) with both ISD and a fixed urethra. Meschia *et al.* included 25 of 301 patients with previous anti-incontinence procedures in their series using TVT, and demonstrated a lower cure rate of 72% for recurrent versus 89% for primary treatment [52]. Biggs *et al.* showed successful use of a transobturator sling in women with failed prior surgery for SUI. In a series of 27 women with urethral hypermobility who underwent TVT-O they reported an 80% success rate assessed by PGI-I (very much better or much better) at mean follow-up of 25.7 months [53]. Stav *et al.* recently showed that repeat placement of a mid-urethral sling resulted in a lower subjective cure rate than primary placement (62% vs 86%) [54]. They also showed that a repeat retropubic sling was more successful than a repeat transobturator sling (71% vs 48%). Both these results may in part be due to the higher rate of ISD in repeat candidates (31% vs 13%). Also of note, the rates of *de novo* urgency (30% vs 14%) and *de novo* urgency incontinence (22% vs 5%) were higher in the repeat group.

Concomitant prolapse surgery/hysterectomy

Groutz *et al.* published their series of 100 clinically continent women with occult SUI with prolapse reduction [55]. At mean follow-up of 27 months, results were comparable with "index" patients. Only two patients had symptomatic SUI at 1 year. In addition, perioperative morbidity was low, with only two patients requiring catheterization of more than 7 days and *de novo* urgency in 8%, which is comparable with sling-only series. Liang *et al.* reported a series of patients undergoing hysterectomy and prolapse repair with pessary reduction of the prolapse during preoperative urodynamic testing [56]. Patients with a positive pessary test (occult SUI) were randomized to TVT or no TVT. The rate of postoperative subjective SUI was significantly lower in those who had a TVT placed (10% vs 65%). No patients with a negative pessary test (none had a sling) had postoperative SUI. A previous prospective trial with 3-year follow up by Meltoma *et al.*, found that concomitant vaginal surgery did not affect outcome of TVT; however, there was an increased rate of complications such as infection, bladder perforation, and transient retention after TVT [57]. Ballert *et al.* used urodynamics to decide which patients should have a MUSS placed with prolapse repair [58]. Patients who had urodynamic-proved SUI and occult SUI (with the prolapse reduced, SUI demonstrated

during urodynamic study) had a MUSS placed. There is an ongoing trial addressing prophylactic sling placement, the OPUS trial [59].

Based on the currently available literature, it would appear that MUSS is a good choice for the treatment of concomitant SUI and prolapse, and may also be effective in reducing the risk of postoperative SUI in women with occult SUI.

Intrinsic sphincter deficiency

ISD represents the portion of SUI that is not due to a support defect or urethral mobility. ISD is difficult to quantify and even more difficult to diagnose in patients who also have urethral mobility. Most of the literature has used a definition of an abdominal leak point pressure (ALPP) of less than 60 cmH_2O or a maximum urethral closure pressure (MUCP) of less than 20 cmH_2O. While we would agree that these lower resistance urethras are probably more difficult to treat, it cannot be said with certainty that the lower resistance is due to ISD rather than a support defect (except in the fixed urethra). Nevertheless the literature has made that distinction and for the purpose of this review we will accept these criteria. More recently, ISD and urethral hypermobility have been viewed as a spectrum of disease with overlap. Thus, recent research examines the contributions of ISD *and* urethral hypermobility to outcomes.

Retropubic MUSS has been shown to be effective in treating this group of patients. Rezapour *et al*. reported on their long-term results in patients with ISD, defined as MUCP less than 20 cmH_2O, at 2 years, with cure rates of 74%, improved 12.5%, and no change 12% [60]. These results compare favorably with their and other authors' results for all comers with SUI. There are five studies (one cohort, one retrospective review, and three randomized trials) that favor retropubic over transobturator MUSS, and one RCT showing equivalence in patients with ISD [61] (variably defined as MUCP < 20 cmH_2O or ALPP < 60 cmH_2O). Fritel *et al*. showed that TVT was most effective in treating the hypermobile urethra, but had acceptable success rates for the relatively fixed urethra also [62]. Success rates at 9 months were 97% with the Q-tip test at greater than 60°, 86% at 30–60°, and 70% at less than 30°. There was no difference in success based on MUCP greater or less than 20 cmH_2O. A recent small study (n = 65) by Haliloglu *et al.* of urethral hypermobility (Q-tip test ≥30°) and ISD (ALPP < 60 cmH_2O) with TOT found that cure rates at 24 months (defined as a negative cough test) were: urethral hypermobility, no ISD 96.4% (n = 31); urethral hypermobility and ISD 87.5% (n = 18); and no urethral hypermobility and ISD 66.7% (n = 16) [63]. They concluded that a lack of urethral hypermobility may be a risk factor for TOT failure and suggested that even in the presence of low leak point pressures suggestive of ISD, the coexistence of urethral hypermobility still indicates likely good outcomes with transobturator MUSS.

Based on the available data it would appear that MUSS, retropubic or transobturator, works well in cases of low urethral resistance with hypermobility. The literature suggests that ISD patients may do better with retropubic MUSS, but the evidence for this is not strong enough to support a high-level recommendation. In cases of a more fixed urethra, there are more data to support the retropubic approach over the transobturator approach, but again the level of recommendation would be relatively low.

Single-incision slings

Although retropubic and transobturator MUSS are considered minimally invasive procedures, there have been more recent developments to make the procedures even less invasive. The single incision or "mini-slings" slings are designed to be placed via a small vaginal incision (like the traditional MUSS) but without any exit incisions. Theses sling can be place like a "hammock" (mimicking the transobturator slings) or like a "U" (mimicking retropubic slings) (see Chapter 142). There are a number of single-incision slings available, and new ones are constantly being introduced. The original single-incision slings and the ones for which some data are available are the TVT-Secur (Ethicon Women's Health & Urology, Somerville, NJ, USA), and the MiniArc (American Medical Systems Inc, Minnetonka, MN, USA),. The TVT-Secur can be placed into the endopelvic fascia in a U form or into the obturator internus muscle in a hammock form, while the MiniArc is placed only as a hammock.

To date there is a paucity of peer-reviewed publications and level 1 evidence in this emerging area. Available data are short term only with mixed results, with some studies demonstrating equivalent cure rates to traditional transobturator and retropubic approaches and others showing less favorable results (Table 143.2). There are no peer-reviewed published level 1 comparative trails of single-incision slings versus traditional MUSS, to establish their place in evidence-based practice. In theory, these procedures could offer a quicker recovery, but that is yet to be demonstrated. Notably, there have been case reports of complications despite the extremely minimally invasive nature of the procedure. Masata *et al.* described severe bleeding from the internal obturator muscle following TVT-Secur, with 1 L of blood loss requiring repeat surgical exploration [64].

We believe that single-incision slings hold promise for the treatment of female SUI as they rely on the same principles as other MUSS. At the time of this writing,

Table 143.2 Results of available studies of mini-slings (number of subjects, results, and complications have been pooled from all the listed studies).

Mini-sling	Main study	Number of subjects	Technique	Results	Complications
Contasure Needleless	Navazo *et al.* (2009) [83]	120	Forceps penetrates Ob foramen, grasps pocket. No needles	Cure 84% Failure 8%	Vaginal erosion 2.5% Urinary retention 1.7%
MiniArc	Gauruder-Burmester and Popkin (2009) [84], Moore *et al.* (2009) [85] Debodinance and Delporte (2009) [86, 87]	230	Self-fixating tips in obturator membrane	1-year cure rates: 69.1%, 77%, 94%	*De novo* urge, 36.8% Bladder perforation 1% Hematoma 1% One erosion, one *de novo* urge Urinary retention 1.6%
TVT-Secur	Neuman *et al.* (2008) [88] Martan *et al.* (2009) [89] Oliveira *et al.* (2009) [90] Meschia *et al.* (2011) [91] Gorlero *et al.* (2009) [92]	423		62%, 71%, 81%, 88.6–92% at 1 year	Vaginal perforation 8% first 50 + 12% (other) vaginal trimming 0.6% *de novo* urge One vaginal erosion

evaluation of these techniques is hampered by short follow-up, limited data, and mixed outcomes, and so these slings have yet to establish their place in the armamentarium of sling surgery.

Complications and their managementWe will outline the incidence of complications and briefly discuss management for intraoperative complications (bladder, urethral, viscous and vessels injury), immediate postoperative complications (voiding dysfunction, groin pain, infection), and chronic problems (*de novo* urgency, sling erosion/extrusion).

Bladder perforation

Bladder perforation occurs in approximately 3.4% of patients during TVT [24]. Transobturator slings were conceived to reduce the risk of bladder (and vessel) injury by avoiding the retropubic space. Three recent reviews have confirmed this. The recent Cochrane review identified 18 trials reporting on bladder perforation and pooled data to show that TOT had significantly lower rates of bladder injury than retropubic slings (0.3% vs 5.5%). Novara *et al*., in an analysis of nonrandomized data, reported that TOT was statistically less likely to cause perforation than retropubic slings [24], and Latthe *et al*., in their meta-analysis of trials comparing TVT-O and TOT versus TVT, reported ORs of bladder injury of 0.11 and 0.15, respectively [32].

Bladder perforations recognized intraoperatively can be managed by removal and replacement of the tape. Cystoscopic confirmation that the final position is indeed outside the bladder is crucial.

Urethral injury is a rare occurrence with both retropubic and transobturator MUSS. Like bladder injuries, they are treated by removing the tape. In cases of a large injury, consideration should be given to aborting the procedure and allowing urethral healing for 3 months before inserting a new sling.

Vascular and bowel injuries

An important paper was published by Deng *et al.* in 2007 regarding the reporting of major complications after MUSS surgery [65]. They reviewed the literature and compared this to reporting through the Food and Drug Administration (FDA) manufacturer and user facility device experience (MAUDE) database (queried for self-reported complications) for the same time period. Their review of the world literature for 2001–2005 found the rate of major complications to be 0.8%, with no reported deaths. There were a total of 928 complications reported to the MAUDE database in that time

period, of which 161 were major, with 10 resulting in death. Notable differences were noted, with 36 serious vascular injuries and 38 bowel injuries in the MAUDE database, but only two vascular and three bowel injuries reported in the literature for 2001–2005.

Vascular injury occurs very rarely; however, it is a devastating complication for a QoL procedure. National registries provide the best indicators of worldwide incidence, and these were reviewed by Sivanesan *et al*. [66, 67]. The reported incidences of vascular injury were: 0% (of 1455) in the Finnish registry, 0.8% (of 5578) (reintervention or conversion rate) in the Austrian registry, 0.03% (of 2280) in the French registry, and 0.1% (of 809) in the Dutch registry [68].

Management depends on the patient's hemodynamic status; in those who are stable, angiographic embolization avoids further operative morbidity, while those who are unstable may require laparotomy and control of bleeding.

Bowel injury is also a very rare complication in the literature, estimated at less than 1%. Two cases occurred among 12 280 cases in the French registry for TVT [68]. Ten cases were reported after TVT in the FDA MAUDE database. In Daneghasri *et al.*'s review of complications in 2008, six deaths had resulted from bowel injury [69]. No cases of bowel injury have been reported after TOT.

Voiding dysfunction and obstruction

Varying rates of voiding dysfunction have been reported after sling surgery. The Cochrane review found that transobturator slings had a lower incidence than retropubic slings (4% vs 7%) [23]. Patients may present early with retention, or late with obstructive voiding symptoms: feeling of incomplete emptying, straining or hesitancy, needing to lean forward or stand, partial or complete urinary retention, or symptoms suggesting overflow incontinence. Symptoms of *de novo* urge may be secondary to urethral obstruction and while not absolute indicators in themselves of voiding dysfunction, refractory symptoms with timing associated with intervention or association with voiding symptoms should alert the physician to the possibility of obstruction. It is especially important to document the relationship of symptom onset to surgery. If patients report symptoms of voiding dysfunction, a free flow rate should be measured. The necessity of urodynamics in this setting is controversial. We would not consider them to be always necessary in the setting of classic obstructive voiding symptoms, retention, or high postvoid residual (PVR) (with normal preoperative PVR) (unpublished data). However, video urodynamics are useful in patients with storage symptoms to determine whether obstruction is present at the level of the sling.

Conservative management includes observation for irritative/storage symptoms and clean intermittent self-catheterization for high PVR and retention. Small series have been published reporting techniques and outcomes for sling loosening/lysis. Klutke *et al*. described 17 patients (2.8% of a 600 patient series) who presented with obstructive symptoms following TVT [70]. The time to sling loosening or cutting ranged from 6 to 228 days. Two techniques were used in this study: the "Washington University" technique uses a right-angled clamp to identify the sling which is then transected, and the "Minneapolis" technique, in which sling is identified and loosened with Metzenbaum scissors with downward traction without sling transection. All 17 patients in this series had immediate postoperative relief of symptoms with ability to void. One patient had recurrence of stress incontinence.

Rardin *et al*. described 23 patients with persistent voiding dysfunction (1.9% of 1175) who underwent TVT [71]. The mean interval between TVT placement and release was 17.3 weeks. In this study, all tapes were transected or segmentally excised. Presenting symptoms were impaired bladder emptying in 20, three had severe irritative symptoms, and seven had both. Seven patients had urethral dilation after TVT placement without resolution of symptoms. Resolution of voiding symptoms differed by symptom. Impaired emptying resolved in all cases, but complete resolution of irritative symptoms occurred in only 30% of cases at 6 weeks, the study endpoint. Stress incontinence recurred partially in 26% and completely in 13% of patients.

Patients with storage/irritative symptoms should also be warned that in a study of 44 patients undergoing sling take down or urethrolysis, two-thirds of patients with preoperative storage/irritative symptoms still had them postoperatively. Only 14 patients with suburethral synthetic slings (all TVT) were included in this study, so the numbers may not be sufficient to draw conclusions from this study alone [72].

With respect to timing of sling loosening or cutting, we favor an approach of early tape loosening for severe obstructive symptoms and retention. Several small series now suggest that early intervention should be favored as delayed intervention may lead to irreversible bladder symptoms. Leng *et al*. published a series of 21 patients who underwent sling lysis. When they stratified patients by their postoperative symptoms or absence of these, there was a statistically significant difference in mean time to sling lysis (9 months in the no symptom vs 31 months in the persistent symptom group) [73]. South *et al*. showed a similar trend, although their series had relatively small number of cases of synthetic slings [74].

Nguyen published his series of 10 women who underwent tape loosening (under anesthesia) at 3–10

days. All the women were spontaneously voiding after this procedure and there were no recurrences of obstruction or SUI at 1-year follow-up [75]. Price *et al*. recently published their series of 33 women who had early sling loosening (mean 7.7 days) under general anesthesia [76]. This was successful in 29 women, with four requiring tape division at 4–8 months. All patients had resolution of voiding symptoms, with one of the four tape-division patients having the only recurrence of stress incontinence.

We consider intervention for patients who have retention or near retention at 1–2 weeks. For early intervention, sling loosening in the office or operating room can be considered. We perform this procedure in a similar fashion under local anesthesia in the office and have found this to be well tolerated. After injection of local anesthesia, the incision is opened by removing the prior closure suture. The sling is hooked with a clamp and the clamp is spread. If this fails to loosen the sling, it can be cut. Animal studies have shown fibroblast infiltration of the tape at 1 week, which supports Price *et al*.'s observation that tapes cannot be loosened after 2 weeks. At this point, it is easiest to cut the tape in the operating room setting.

For persistent voiding dysfunction after a MUSS has been formally cut, a formal transvaginal urethrolysis is the next step. It can be done through a midline vaginal incision. Fortunately, this is rarely required.

Groin pain

Groin pain may occur after transobturator slings, has been reported but is rare after retropubic slings. In Latthe *et al*.'s systematic review, this occurred in 12% of the transobturator group compared to 0.9% of the TVT group (OR = 8.28). Similarly the Cochrane review found a 12% incidence of groin pain in the TOT group versus 1.7% in the retropubic group (RR = 6) [36]. The differential diagnosis of persistent groin pain after TOT includes: adductor muscle strain, osteitis pubis, obturator/groin abscess, structural adhesions, and inflammation, edema or nerve entrapment of the anterior branch of the obturator nerve. There is a limited amount of literature regarding treatment of pain.

Work-up should include examination and laboratory tests to exclude hematoma and infection. MRI can visualize edema, hemorrhage, and the obturator nerve itself; however, it cannot see the polypropylene tape or smaller branches of the nerve. Described management includes pain medications, steroids, and excision of part or all of the sling Hazewinkels *et al.* advised against delaying sling removal, as further scar tissue deposition can hamper removal and nerve damage may become irreversible [77].

Infection

Seven cases of abscess (associated with vaginal erosion) following TOT placement were reported in the Austrian registry [78]. The authors concluded that these seemed to be more common after transobturator than retropubic tapes; however, four of the abscesses were associated with the ObTape, a 50-μm pore tape that has been removed from market [78]. Infections are rare with the current type 1 macroporous meshes. Treatment requires complete excision of the infected tape.

Lower urinary tract symptoms

De novo urgency can occur following sling surgery with rates ranging from 3% to 25.9%. Holmgren *et al*. reported on a series at a mean follow-up of 5.6 years and discussed several important findings [79]; patients with urgency will experience lower quality even if their stress incontinence is cured, urgency incontinence may not be reported in sling failure rates, and urgency symptoms may not be transient (in fact the proportion of the group with urgency remained consistent over time). They compared women with and without *de novo* urgency and showed there were large and significant differences in QoL scores; the women with *de novo* urgency had an IIQ-7 of 28.1, as compared to 5.6 for those in the comparison group ($P = .0001$). For the UDI-6, the corresponding rates were 49.6 and 13.6, respectively ($P = .0001$). They discussed that persistent incontinence, now of the urgency type, may not be reported as failure in many series where success is the absence of leakage on stress testing or patient reported stress incontinence, although they noted that urge and urgency incontinence may be more bothersome to women in everyday life than stress incontinence. In their series, 51 of 67 patients with *de novo* urgency in this series had actual episodes of incontinence. While most authors report that *de novo* urgency will be transient, these authors showed that 14.5% of women experienced this symptom with similar frequency across a duration of 2–8 years after TVT surgery.

Transobsturator slings have a lower rate of storage symptoms, with pooled results from eight RCTs comparing retropubic to transobtrurator approaches showing an OR of 1.81 [23].

Vaginal erosion/extrusion

The rate of vaginal erosion/extrusion is reported at 1%. The Cochrane review found that the vaginal extrusion rate was higher in the TOT than the TVT group (OR = 1.51; 95% CI 0.51–4.43) [23]. On subgroup analysis, the erosion was seen more often in the TOT group (OR = 2.37, 95% CI 0.53–10.63) and less often in the

TVT-O group (OR = 0.86; 95% CI 0.17–4.35) when compared with TVT.. Lathe *et al*. also found the transobturator path to have a higher risk of vaginal injury (OR = 3.58) [32].

Similar to bladder mesh erosion, some vaginal erosions may represent unreognized vaginal perforation (especially at the vaginal fornices) intraoperatively.

Symptoms of vaginal extrusion include malodorous vaginal discharge, postcoital spotting, dyspareunia (patient and partner), vaginal bleeding, and UTIs.

Management of extrusion optimally involves surgical removal of that portion of the tape. Some have described trying a course of conservative therapy with estrogen cream.

Sexual function

Several studies show equivalent results for sexual function after TOT and retropubic slings. They also demonstrate that while there are significant numbers of women who improve (29–32%), there are also some who deteriorate following anti-incontinence surgery 12.5–17.3%), with no difference demonstrated by Senthilhes *et al.* in their recent comparison between transobturator and retropubic synthetic slings [80].

Bladder and urethral erosion

Fortunately erosion of MUSS into the bladder or urethra is a rare occurrence. When it is recognized, the first question that must be asked is whether it is a true erosion or a missed injury. In 14 randomized trials reviewed by Novara *et al*, only three reported on this, with rates from 0% to 1.8% for transobtruator and 0% to –1.9% for retropubic slings. In 34 nonrandomized trials of TVT with at least 24-month follow-up, four reported on this with similar rates ranging from 0% to 1.8% [24]. Many authors believe that erosion into the bladder actually represents slings inadvertently placed through or in the wall of the bladder at the time of surgery. McLennan *et al.* demonstrated a learning curve with respect to bladder perforation [81]. Residents' cases were grouped into numbers of five; the rate of injury in the first five was 40.9%, 30.7% in second five, and 25.9% in the third five; the differences were statistically significant. Overall, there was a significant rate of missed perforation on cystoscopy with 35 of the 95 injuries missed by residents (37%). This emphasizes the need for thorough cystoscopic examination at the time of surgery, to avoid missed perforations which present as "bladder erosions" [81]. Such injuries may present with UTIs, bleeding or bladder stones. Treatment requires removal of the sling from the bladder. Endoscopic techniques with endoscopic scissors and laser, laparoscopic techniques via the bladder, and open excision are used.

A recent series of 14 urethral injuries following sling surgery was published by Morton and Hilton [82]. Their patients had undergone TVT, SPARC, TOT, and TVT-O types of slings. Their pathologies included six perforations/erosions, four diverticula, and four urethrovaginal fistulas. Most of the patients had had abnormal symptoms following sling insertion, including urinary retention, persistent incontinence or obstructed voiding. Each of these patients required reconstructive surgery, with seven of 14 having significant persistence of overactive bladder symptoms, one voiding difficulty, and one persistent groin pain. These authors also performed a literature search for further cases, finding four further reports of urethral diverticula and 15 urogenital fistulas. The authors used case series report of urethral perforation to calculate rates of urethral perforation: 0.88% for retropubic slings and 1.09% for transobturator slings. Whilst the authors acknowledge that it is difficult to determine the true denominator, they conclude that the incidence of urethral injury appears no lower for the transobturator than the retropubic route. Thus, they emphasize the importance of operative cystoscopy in all types of slings.

The mechanism by which urethral erosion occurs is probably dissection into the incorrect anatomic planes around the urethra where dissection is too close to the urethra within the periurethral fascia or if the sling is placed under tension, . Data from the Austrian registry reported urethra/bladder erosion in 0.5% [78].

Urethral erosion requires removal of the eroded portion of sling and primary closure or urethral reconstruction with vaginal/martius flaps.

Conclusions

MUSS have revolutionized female incontinence surgery. From their inception they offered comparable efficacy to existing operations with improved ease of performance for the surgeon and improved postoperative morbidity for the patient. These results have proven durable in the long term. Further innovation of the technique includes the emergence of transobturator and mini-slings. Whilst complications of these slings are relatively rare, surgeons who perform these operations should mindful of their symptoms so that management of these is expedient.

CHAPTER 144

Maxi/Pubovaginal Sling

Bhavin Patel & Gopal Badlani

Department of Urology, Wake Forest University Baptist Medical Center, Winston Salem, NC, USA

Introduction

DeLancey proposed the hammock theory of urethral support in 1995 [1]. In his description he maintained that continence is the result of compression of the urethra and bladder neck by a hammock-like musculofascial layer. When this layer is deficient, funneling of the bladder neck during increased intra-abdominal pressures results in incontinence. The aim of the pubovaginal sling (PVS) is to restore the musculofascial support by reinforcing the urethra. This allows for kinking during times of increased abdominal pressure, thereby preserving continence.

Historical perspective

Although DeLancey described the hammock theory in 1995, the first description of treating stress urinary incontinence (SUI) with suburethral/bladder neck support occurred over 100 years ago. It was in Paris, in 1907, that Giordano first described using graft material, specifically gracillus muscle, as a urtheral/bladder neck sling to treat incontinence [2]. Later, in 1910, Goebell used pyrimidalis muscle to create this suburethral sling [3], and in 1933, Price used fasica lata as sling support of the urethra [4]. The process continued to evolve.

In 1978, McGuire and Lytton popularized the autologous fascial sling by reporting on their experience of 52 cases [5]. Their technique described the harvest and use of a 1×12-cm piece of rectus fascia to support the urethra. They had an 80% success rate at a mean follow-up of over 2 years. In the late 1990s, Blaivas modernized the procedure as he showed that all forms of SUI could be addressed with an autologous rectus fascial sling [6]. Prior to this, its application was limited to type 3 SUI only.

Diagnosis

Patients with SUI present with the complaint of involuntary urinary loss with increased intra-abdominal pressures, such as with coughing, laughing and Valsalva test. The diagnosis can be made based on history and physical examination alone, and quantified with a pad test. Attention should be paid to any associated prolapse, presence or absence of urethral hypermobility, symptoms of overactive bladder, urge incontinence, or significant postvoid residual (PVR) urine. The utility of urodynamic testing is debatable in the diagnosis of primary SUI; however, it is helpful in cases who are not as straightforward and in those complicated by the aforementioned pathologies, and it is required in recurrent SUI after failed surgery. In patients with associated vaginal prolapse, the SUI may be occult and become evident with the reduction of the prolapse. Patients with overactive bladder and or urge incontinence may not improve with a mid-urethral sling, and may actually get worse [7]. Finally, patients with PVR urine, depending upon its etiology, should be counseled regarding an increased risk of urinary retention after a sling procedure.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Surgical indications

PVS is indicated in the treatment of SUI, whether from intrinsic sphincter deficiency or urethral hypermobility. Other indications include the treatment of incontinence after prolonged indwelling catheter drainage [8], incontinence after pelvic or urethral trauma [9] (where placement of synthetic mesh may lead to an unacceptably high rate of urethral erosion), and for continent support at the time of vesicovaginal fistula [10] or urethral diverticulum repair [11]. Finally, PVS can be used to augment continence after a bladder-neck reconstruction [12].

Of note, prior vaginal surgery is not an absolute contraindication to PVS; however, it can make the surgery technically challenging. Further, PVS can be done safely and effectively at the time of pelvic organ prolapse repair [13].

Surgical alternatives

The surgical alternatives to PVS for the treatment of SUI include transvaginal plication, retropubic suspensions, mid-urethral slings, artificial urinary sphincters, urethral bulking agents, and radiofrequency ablation. Nonsurgical therapies include pessaries, indwelling catheters, pads, and medical therapy.

Choice of material

The materials available to the surgeon for PVS are autologous tissue, allograft, xenograft, and synthetic meshes.

Synthetic meshes

The use of synthetic meshes obviates the need for autologous fascial harvest and thereby has the advantage of decreasing operative times. Also, as these are nonbiologically derived material, there is no risk of disease transmission. Furthermore, nonabsorbable meshes are not degraded like the biologic materials and maintain their strength over time. These advantages need to be weighed against the real risks of vaginal extrusion and urinary tract erosions. This is our material of choice and we use an off-the-shelf piece of prolene mesh that is cut into a strip measuring 2×7 cm.

Allografts

Like synthetic meshes, allografts do not require fascial harvest and similarly have the advantage of decreased operative times, decreased postoperative pain, and a shorter convalescence. Additionally, they are readily available as an off-the-shelf material that can be used as needed. Allograft materials have lower erosion and extrusion rates compared to synthetic meshes [14], but these advantages must be weighed against the higher cost of allografts compared to mesh, and the theoretical risk of disease transmission. Another potential disadvantage is that different allografts may have different biomechanical properties based on differences in cadaver harvest or tissue processing. Our allograft of choice is Tutoplast (Mentor Corporation, Santa Barbara, CA, USA), which is fashioned into a strip measuring 2×7 cm.

Xenograft

Commonly used xenografts for PVS include material derived from porcine dermis (Pelvicol; CR Bard Inc, Murray Hill, NJ, USA) or porcine small bowel (SIS™; CR Bard Inc). They are readily available as off-the-shelf materials that can be used as needed. These materials have the same disadvantages as allografts, particularly higher product costs, biomechanical variability, and a theoretical risk of disease transmission.

Autologous tissue

These are obtained, as the name implies, from the patients themselves. These tissues require more operative time to procure, and increase perioperative and postoperative morbidity and convalescence [15]. Furthermore, the quality and strength of the harvested autologous tissue is variable, depending on the patient's age, medical comorbidity, and previous surgeries. Despite these disadvantages, autologous tissues are the material of choice of many surgeons as they are completely biocompatible and have no risk of erosion or extrusion. The two most commonly used tissues are fascia lata and rectus fascia. Grafts using the anterior vaginal wall have also been described, but are discussed elsewhere.

Fascia lata

The use of fascia lata as a sling material was initially described by Price for sacral agenesis [4]. It was popularized as a material for suburethral slings in the treatment of incontinence by Beck *et al.* [16]. The theoretical advantages of fascia lata over rectus fascia are that fascia lata is less affected by previous abdominal surgery, patients with this sling material are less prone to abdominal wall hernias, and it has greater tensile strength. The disadvantages of fascia lata are the time required for harvest, harvest site pain/disability, need for patient repositioning, and the operative field is not one usually employed by urologists.

There are many different techniques to harvest fascia lata for use in PVS. Our preference has been to use the technique described by Govier *et al.* [17], which is out-

lined here. The patient is placed in the full lateral position with the entire thigh, from the iliac crest to the tibial plateau being prepped and draped into the surgical field. A vertical line is drawn from the greater tronchanter of the femur to the medial condyle of the knee. A 3-cm perpendicular incision is made at the mid point of this line. Two additional perpendicular incisions of 3 cm in length are made, flanking the first incision 9 cm superior and inferior (Figure 144.1). Via these incisions the fascia lata is cleared off from the overlying subcutaneous fat. At the three skin incision sites, incisions parallel to the direction of the fascial fibers are made 2.5 cm apart. At the distal and proximal ends of the fascia, two stay sutures are placed perpendicular to the fibers of the fascia and the fascial incisions are connected to free a piece of fascia lata approximately 24 cm in length and 2.5 cm in width. Hemostasis is achieved, the fascia lata is not approximated, and the skin is closed with a stapler. The leg is then wrapped with an elastic dressing, which is removed 8 h postoperatively, and early ambulation is required of all patients.

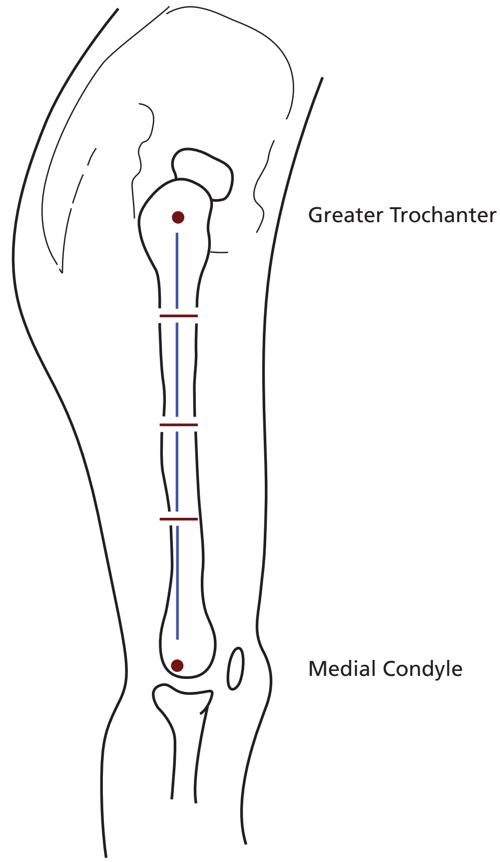

Figure 144.1 Skin incisions for fascia lata harvest.

Rectus fascia

Rectus fascia is our autologous material of choice as it is in the surgical field and thus is easily procured. To obtain the sling, a low transverse abdominal incision is made. Dissection is carried down to the level of the anterior rectus fascia and the fascia is cleaned of overlying fat. The intended fascial incision is marked with a marker pen; the marked fascia should be 1 cm in width and 12 cm in length, noting the inferior portion is at least 5 cm from the pubic symphysis. Two stay sutures are placed at the distal ends of the fascia, perpendicular to the fascial fibers. With traction on the stay sutures, the fascial strip is then mobilized with a combination of sharp and blunt dissection (Figure 144.2). The defect in the fascia is then closed in a running fashion with delayed absorbable suture.

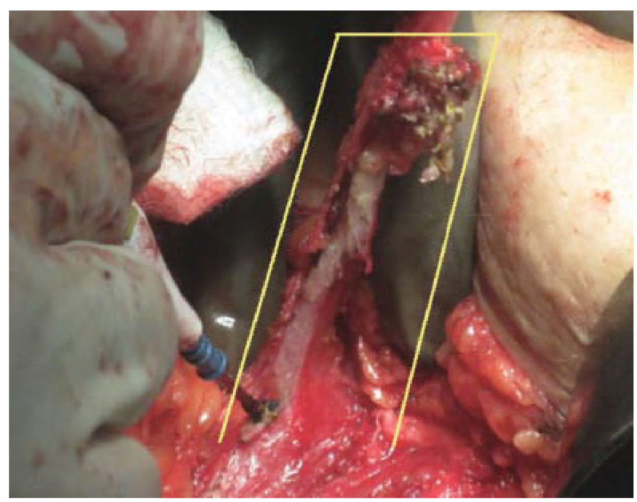

Figure 144.2 Rectus fascia sling mobilization.

Preoperative preparation

In the absence of contraindication, estrogen cream is prescribed for 4–6 weeks pre-operatively in postmenopausal patients with vaginal epithelial atrophy. If the patient uses a pessary, it is discontinued 2 weeks prior to surgery. All forms of anticoagulation, including "baby" Aspirin, must be stopped with sufficient time to allow for normalization of bleeding parameters. Preoperative complete blood count, basic metabolic panel, coagulation studies, urinalysis and urine culture are obtained. In the presence of a urinary tract infection, coagulopathy or other significant medical abnormality, surgery is postponed. If constipation is present preoperatively, the patient is placed on an aggressive bowel regimen in the weeks preceding surgery. The patient is then made nil per mouth at midnight on the evening prior to surgery. Based on the American Urological Association (AUA) guidelines for surgical prophylaxis, a first- or second-generation cephalosporin is given intravenously in the anesthesia holding room at least 1 h prior to surgery and continued for a total of 24 h.

Operative technique

Once moved to the operating table, sequential compression devices are placed on the lower extremities and general endotracheal anesthetic is induced. The patient is then positioned in the dorsal lithotomy position using Allen Yellofin stirrups. The abdomen, pubis, and perineal area are shaved using clippers and then prepped with chlorhexidine-based chemical antiseptic. The patient is then draped with the Lingeman Gyn surgery drape (Microteck Medical, Columbus, MS, USA). A 16F urethral catheter is placed in the urethra and the balloon is inflated to help facilitate identification of the bladder neck. A Lone Star surgical retractor is used to retract the labia and open the introitus for exposure. A weighted speculum is placed to retract the posterior fourchet.

An Allis clamp is placed at the hymen ring along the anterior vagina and ¼% bupivacaine (Marcaine) with epinephrine is injected from 1 cm proximal to the urethral meatus to the bladder neck, for hydrodistention. A 4-cm midline incision is made over the bladder neck with the Foley balloon used as a guide. Curved Metzenbaum scissors are used to dissect thick flaps of anterior vaginal wall epithelium in an anterolateral fashion, toward the ipsilateral shoulder, until the endopelvic fascia is reached. The Foley catheter and balloon should be constantly used as a guide to the urethra and bladder neck. The depth of dissection is marked by a "bloodless" plane. At this point, with either the curved Metzenbaum scissors or blunt finger dissection, the endopelvic fascia is perforated bilaterally. A packing sponge is placed in the vagina and attention is turned to the lower abdominal incision.

A 10-cm Pfannenstiel incision is made one finger breadth superior to the symphysis pubis. Using cautery, the dissection is carried through Camper's and Scarpa's fascia, and the anterior rectus fascia is identified. Using sharp and blunt dissection, the fascia is cleaned of the overlying fatty tissues. A scar-free area of the fascia at least 5 cm above the symphysis pubis is chosen (to aid in closure). As described above for procuring rectus fascia, the sling material is dissected such that a 12 × 1 cm rectus fascial sling is made. At the lateral aspect of the sling, the holding sutures are exchanged for 0-prolene sutures, with a figure-of-eight suture placed 0.5 cm from the lateral margin of the sling on each side. At the midline of the sling, using a surgical marker, a vertical line is drawn. The sling is then placed in a bath of normal saline with bacitracin antibiotic.

After ensuring complete decompression of the bladder, at 2 cm above the symphysis pubis, the lateral aspect of the rectus muscle is identified and retracted medially. The underlying transverse fascia is perforated bilaterally and connected to the vaginal incision. As this space is being developed with ether blunt or sharp dissection, it is important to stay directly on the posterior surface of the pubis to avoid injury to vessels or the bladder.

The sling is then placed in the anterior vaginal dissection and, using two long curved clamps, the holding sutures on the lateral aspect of the sling are brought to the abdominal incision through the tunnels created lateral to the rectus muscle. Hemostats are placed on each set of holding sutures laterally. A 4-0 Vicryl suture is used to fix the midline of the sling, previously marked, to the midline periurethral tissue at the bladder neck. The vaginal incision is closed with 3-0 PDS suture and an estrogen cream-soaked vaginal pack is placed in the vagina.

A tonsil clamp is used to make two perforations in the rectus fascia lateral to where the sling was procured. The holding sutures are tunneled through these openings ipsilaterally. The rectus fascia is then closed using 0 PDS sutures in a running fashion. The sling-holding sutures are tied to each other over the now closed fascial incision. The tensioning of the sling sutures is such that one finger should be able to be placed between the rectus fascia and the sling sutures in the midline before any movement of the bladder neck occurs. This is obviously one of the most important parts of the operation; as a sling that is too loose will result in continues incontinence and a sling that is too tight will result in retention. The skin is then closed with a 4-0 Monocryl suture.

Postoperative care

A complete blood count is ordered in the postoperative anesthesia care unit and in the morning of postoperative day 1. After reviewing the hemoglobin, on postoperative day 1 the vaginal packing and the catheter are removed and the patient is given a voiding trial. If there is significant residual urine, the patient is taught clean intermittent catheterization. At this point the patient is discharged home with stool softeners and oral narcotics. They are given explicit instructions to avoid vaginal penetrative intercourse and heavy lifting for 6 weeks. They return for follow-up in 6 weeks to assess postoperative results and voiding parameters.

Clinical results

Synthetic slings

A review of the literature regarding the uses of polypropelene mesh, our material of choice, as the sling material for PVS revealed a paucity of long-term studies. The two published large-volume, long-term studies (Table 144.1) report an overall cure rate for synthetic PVS (using poly-

propelene) of approximately 81% with over 90% being cured or improved.

Allograft slings

As allograft materials have become readily available, their use as a sling material in PVS has increased. As mentioned previously, the decreased morbidity and the decreased operative time associated with allograft slings compared to autologous slings make them a favorable choice. Published reports for allograft fascial slings in the last 10 years are shown in Table 144.1.

Xenograft slings

Xenograft slings have only recently become widely available for use in the USA. Although the number of published reports on their use as sling material in PVS is low, their short- and longer-term results appear promising (Table 144.1).

Autologous fascia

There are most studies and long-term results for the use of autologous tissues for sling material in PVS. The long-term results are good and they are often the benchmark to which other slings are compared (Table 144.1).

Complications

Intraoperative complications

Intraoperative complications such as bladder injury, urethral injury, bowel injury, and hemorrhagic complications from injury to blood vessels can all occur. Although serious injuries and mortality during PVS procedure are exceedingly uncommon, the surgeon must remain vigilant during and after the procedure to identify these problems and address them as they arise.

N/A, not available.

Harvest site complications

These are associated with autologous fascial slings. They include harvest site hernias [18] and leg pain [17]. These complications are rare and are often reported as single cases in larger series. In the case of hernia, if symptomatic, surgical repair is indicated [18]. In the reported case of postoperative leg pain after a fascia lata sling, the pain resolved with physical therapy [17].

Persistent stress incontinence

Despite the high success rates of PVS, regardless of the material used, persistent stress incontinence can remain. When this occurs it is important to get an accurate assessment of the degree of leakage that is occurring by quantifying it. Furthermore, urodynamic evaluation is also important in ruling out urge incontinence and determining leak point pressures. Based on the degree of bother, pad usage, and leak point pressure treatments, including timed voiding, the off-label use of duloxetine, urethral bulking agents, or sling revision can be discussed.

De novo urinary urgency

This is a troubling problem after PVS. The incidence of postoperative *de novo* urinary urgency is variable and has been reported to occur in patients at a rate of 5–44% [19]. *De novo* urinary urgency often responds to anticholinergic medications. When this fails, other treatments, including pelvic floor rehabilitation, sacral neuromodulation, botulinum toxin, imipramine, may be considered.

Urinary retention

This is the result of anatomic or functional obstruction when the sling is tied with excessive tension. The rate of postoperative retention is variable, but in most studies it decreases with time, such that at a year less than 5% of patients have significant postoperative urinary retention [19]. In the immediate postoperative period, urinary retention is managed with clean intermittent catheterization. If it persists pasts 3 months, we perform urodynamic testing and if due to increased outlet resistance, incision of the sling is considered.

Urinary tract erosion and vaginal extrusion

These are feared complications of PVS. Based on a review of over 5000 articles by the AUA Guidelines Panel, the rate of extrusion and erosion for autologous and allograft PVSs was less than 1% [14]. The real concern for extrusion and erosion is with the use of synthetic materials. Earlier used synthetics had an unacceptably high rate of these serious complications. Fortunately, the contemporary use of prolene as synthetic mesh has not been associated with such high erosion and extrusion rates [20]. Most urinary tract erosions occur within 6 months of placement of the sling and often present with hematuria, infections, voiding dysfunction and/or urinary retention. When present, urinary tract erosion mandates removal of all exposed sling material. Vaginal extrusion can occur and often presents with vaginal discharge and/or patient or partner dyspareunia. The extent and bother of the extrusion dictates the treatment, which varies from topical estrogen creams, to segmental sling excision, or flapped vaginal closure.

Conclusions

The aim of the PVS is to restore the musculofascial support by reinforcing the urethra, which serves to restore continence in patients with SUI. Although there is a choice of using autologous, allograft, xenograft, and contemporary synthetic materials for slings, all have good results with acceptably low complication rates.

CHAPTER 145

Mesh Kits for Vaginal Prolapse Surgery

G. Willy Davila

Department of Gynecology, Section of Urogynecology and Reconstructive Pelvic Surgery, Cleveland Clinic Florida, Weston/Fort Lauderdale, FL, USA

Introduction

There has indeed been a revolution in pelvic reconstructive surgery over the past decade. This revolution has occurred in large part due to the growing incidence of genital prolapse and other pelvic floor dysfunctions in women, as well as greater awareness from industry regarding the need for appropriate tools for use by pelvic reconstructive surgeons. As a result, new techniques, materials, and tools have become available and have been marketed widely. As with any rapidly changing medical field, progress has been associated with controversy as reported improved outcomes have been associated with new and yet poorly understood consequences of new approaches, materials, and techniques. In this chapter, we will discuss the evolutionary development of prolapse repair kits utilizing synthetic and biologic graft materials, their reported outcomes, and reported consequences.

Demographic changes in our population are mainly based on increased life expectancy. Thus, there will be an increased number of women with pelvic floor dysfunction presenting to physicians' offices over the next few decades. It has been estimated that the number of women with at least one pelvic floor disorder will increase from 21.8 million to 43.8 million between 2010 and 2050 [1]. The number of women with urinary incontinence will increase by 55% and the number of women with pelvic organ prolapse will increase by 46%, up to a total of 4.9 million women. This increase in prevalence of pelvic floor disorders can seem quite alarming and does require an increased understanding and knowledge of these disorders by clinicians caring for women with pelvic floor disorders. Traditional approaches to genital prolapse have been fraught with lower than acceptable success rates, particularly in the anterior compartment where success rates of less than 50% were frequently reported with traditional midline plication techniques. The evolution of prolapse surgery has followed along the lines of evolution in anti-incontinence surgery. Traditional compensatory procedures were deemed to have less than acceptable results and as a consequence new tools were developed to assist surgeons in their surgical procedures. A clear example is the development of more standardized approaches to stress incontinence, such as the tension-free vaginal tape (TVT) sling procedure, which represented the first kit approach to stress incontinence with a standardized, step-by-step technique. It did not take long for the popularity of the TVT sling procedure to lead to the development of analogous approaches to genital prolapse with standardized mesh and needle-based kits (Figure 145.1).

Thus, the onset of usage of graft kits for prolapse surgery follows a rather rational progression of technologic improvements. Some argue that this progression in new technology development has occurred too rapidly, without time to critically analyze its results and consequences, and thus controversy has arisen.

Who are the appropriate candidates for mesh kit implantation? This question has led to many discussions regarding the indications for mesh kit usage. With a lack of medium- and long-term comparative studies in different population segments, it is in fact difficult to

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

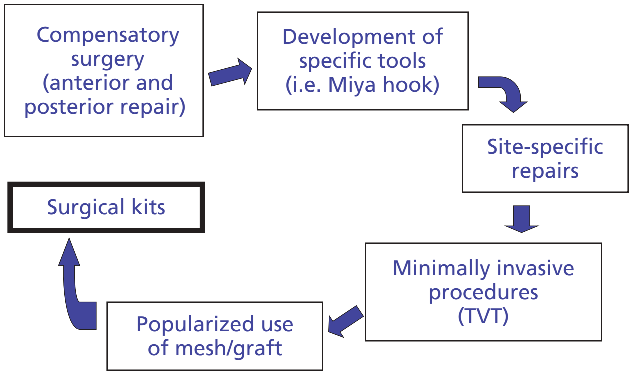

Figure 145.1 Evolution of prolapse surgery. TVT, tension-free tape.

clearly distinguish those patients who may significantly benefit from the mesh kit repair. As experience grows with the use of mesh kits, the risks associated with synthetic mesh kit use have become more apparent and the risk-to-benefit ratio has become clearer. We will discuss this further in this chapter. One thing is likely clear. The failure rate of recurrent prolapse surgery repair is greater than that found with primary prolapse repairs [2]. Thus, patients with recurrent prolapse, especially those with weak fascia or large fascial defects, may particularly benefit from mesh reinforcement during prolapse surgery. Among other accepted indications are patients with chronic increases in intra-abdominal pressure and those with endogenously weak supportive tissues.

Synthetic mesh is used to recreate supportive ligaments (such as with suburethral slings) and replace missing or defective fascia along the anterior and posterior walls. Biologic grafts are typically not of sufficient integrity and strength to replace fascia and thus are primarily utilized to reinforce weakened fascia, such as an overlay to a midline plication of the patient's endogenous fascia. These different applications of synthetic versus biologic grafts are being more clearly understood as published clinical series report differences in outcomes.

Benefits of prolapse repair kits

These include:

• *Standardized surgical procedures.* A standardized, step-by-step procedure allows for quarter predictability of outcomes when a procedure is performed by different surgeons.

• *Comprehensive prolapse repairs.* Repair of apical, anterior, and posterior vaginal prolapse within one surgical procedure is beneficial to the patient by reducing the likelihood of opposite compartment prolapse. The likelihood of sequential surgeries to repair subsequent prolapse is also likely reduced.

• *Time efficiency in the operating room.* Standardized techniques with subfascial dissection have been reported to result in simplified surgeries with greater reported time efficiency and reduced costs.

These theoretical benefits of synthetic mesh kits are associated with concerns regarding the growing widespread implantation of these kits:

• *Patient selection.* Identification of appropriate patients for mesh repairs is crucial to achieving the above desired benefits. The surgeon must thus have sufficient knowledge of anatomy and identification of anatomic defects on physical examination in order to appropriately select patients for kit repairs.

• *Surgeon skills and knowledge.* An unskilled surgeon armed with a surgical kit will still likely have suboptimal outcomes. Thus, surgical kits do not make up for poor surgical technique and skills.

• *Material choices.* Experience has taught us that Type 1 polypropylene mesh (monofilament, macroporous) is the only type of mesh that should be utilized in the pelvis in order to minimize the chances of infection, inflammatory changes and biofilm formation (see Chapter 143). However, within Type 1 mesh materials there are variations in composition and construct, thus leading to a need for greater definition in terms of outcomes based on different types of Type 1 mesh.

• *Complications.* As with any surgical technique, complications are reported with a novel technique. There are indeed specific complications related to synthetic mesh kits. These will be discussed further in this chapter. However, it must be stated that the benefits of kit use should far outweigh any reported complications.

• *Long-term effects.* As with any new surgical technique involving a permanent implant, the greatest concern arises from the long-term impact of a synthetic implant on a patient's quality of life and anatomy. Only time will tell whether there are any significant adverse effects noted years remote from implantation of a synthetic material in the pelvis. Major long-term concerns relate to vaginal anatomy and its impact on sexual function. Specifically, the impact of estrogen deprivation after menopause and stiffening/contraction of mesh may result in long-term sexual dysfunction and possibly difficult-to-treat erosions.

Currently available kits

There are a number of mesh kits currently available for repair of vaginal prolapse. These kits fall into two primary categories.

Trocar-based kits rely on transobturator or transgluteal passage of needles to implant the mesh arms onto the desired anatomic locations (Figure 145.2). These kits include:

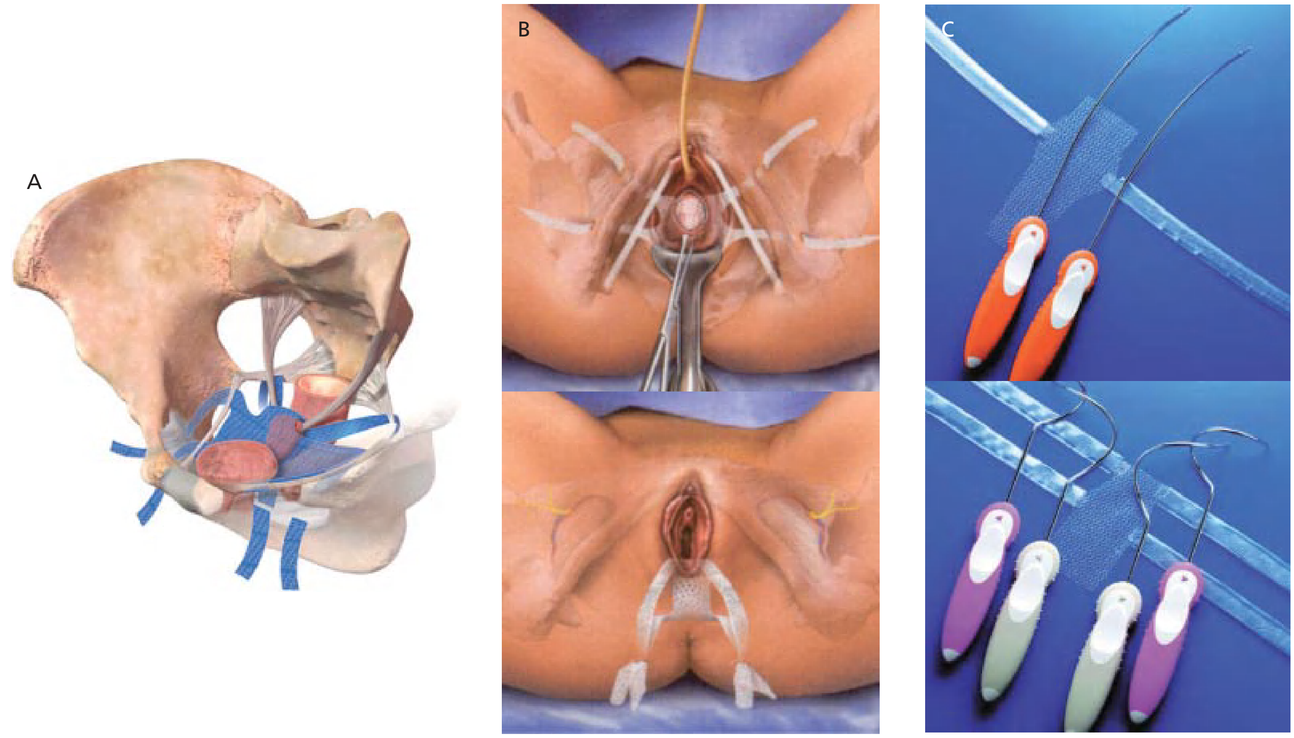

Figure 145.2 Trocar-based mesh kits. (A) Prolift (reproduced courtesy of Ethicon Women's Health & Urology, Somerville, NJ, USA; © ETHICON, Inc. Reproduced with permission.); (B) Avaulta anterior posterior (courtesy of CR Bard Inc, Murray Hill, NJ, USA); (C) Apogee/Perigee (courtesy of American Medical Systems Inc, Minnetonka, MN, USA).

- Prolift: anterior and posterior (Gynecare; Ethicon Women's Health & Urology, Somerville, NJ, USA);
- Apogee (apical and posterior wall) and Perigee (anterior wall) (American Medical Systems Inc, Minnetonka, MN, USA);
- Avaulta anterior and posterior (CR Bard Inc, Murray Hill, NJ, USA).

Internal fixation kits rely on internal fixation onto soft tissue structures without the use of external perineal or perianal incisions (Figure 145.3). These kits include:

- Soft tissue anchor based system: Elevate anterior and posterior (American Medical Systems Inc);
- Pulley suture based systems: Pinnacle and Uphold (Boston Scientific Corporation, Natick, MA, USA).

Composite kits that do not rely solely on Type 1 mesh material incorporate other biologic materials along with the synthetic Type 1 mesh:

- Synthetic tape with biologic non-cross-linked porcine dermal anterior and posterior capes: Apogee and Perigee (American Medical Systems Inc) (Figure 145.4);
- Collagen coating on synthetic polypropylene mesh: Avaulta Plus (CG Bard Inc).

Other kits are also available which are not as widely marketed. These include a prepubic and transobturator placed anterior mesh kit, Nazca TC (Promedon, Cordoba, Argentina); other trocar-based made kits, Ascend (Caldera Medical Inc, Agoura Hills, CA., USA), as well as self-made polypropylene mesh kits used by individual surgeons. Overall, the synthetic polypropylene mesh kits rely on subfascial dissection and fixation to either the sacrospinous ligaments (Prolift posterior, Elevate anterior and posterior, Avaulta posterior, Pinnacle, and Uphold) or soft tissues anterior to the ischial spine at the level of the attachment of the arcus tendineus (Apogee) or obturator membrane and paravaginal support tissues (Perigee, Avaulta, Nazca).

Reported outcomes

As the time of writing, no specific published reports were identified on Avaulta, Pinnacle, Uphold or Nazca.

Prolift

Numerous publications over the past few years have documented expected outcomes with the use of the synthetic Prolift kits for vaginal prolapse. Table 145.1 describes the most commonly reported findings. A large number of subjects have been included in these studies with follow-up of longer than 1 year in many [3–8]. A combination of anterior, posterior, and combined Prolift kits has been utilized with success rates ranging from

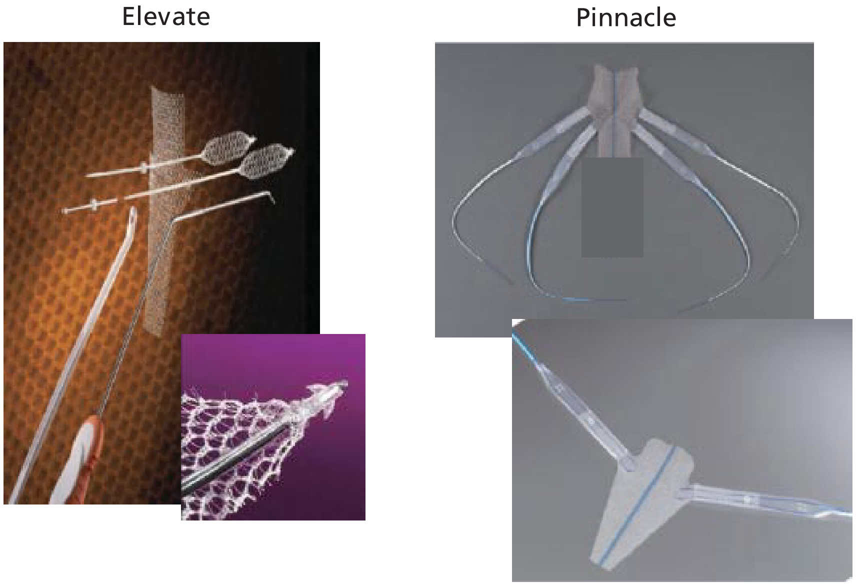

Figure 145.3 Elevate (courtesy of American Medical Systems Inc, Minnetonka, MN, USA) and Pinnacle (courtesy of Boston Scientific Corporation, Natick, MA, USA) internal fixation-based kits.

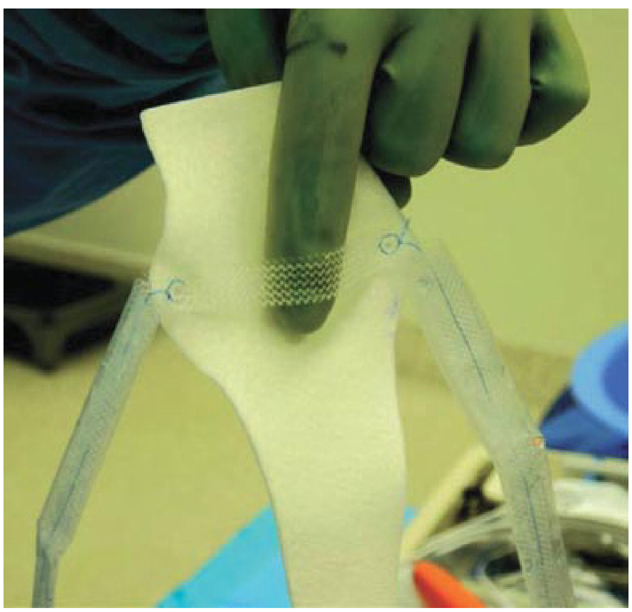

Figure 145.4 Composite synthetic–-biologic kit.

87% to 95%. Complication rates have been reported and will be reviewed in the subsequent section. Overall, the Prolift kit has the longest track record, having been initially described as a total vaginal mesh (TVM). It was developed in France, with outcomes reported on a serial basis by its originators. This group first reported on the original 794 patients (684 TVM and 110 Prolift) [3]. The main changes in construct of the kit involved a softer Prolene mesh as well incorporation of a user-friendly kit with simple-to-use trocar cannulas. This French group also reported on expected outcomes. They noted a significant reduction in erosion rates when a hysterectomy was not performed and thus advocated for uterine preservation with performance of a prolapse repair. In addition, they reported a significantly greater increase in erosion rates when a T-incision was used for the performance of a hysterectomy and anterior prolapse repair. If a hysterectomy is performed, they suggested a linear incision rather than a T-incision for the cuff/anterior vaginal wall.

Perigee/Apogee

Of these two kits, Perigee has been reported on to a greater degree. The synthetic Perigee kit for repair of cystocele was the focus of a recent 2-year follow-up prospective multicenter trial reporting a success rate of 88.5% [9]. This group reported an extrusion rate of 10.5% and pelvic pain in 4.4% of subjects. An earlier report by Garauder-Burmester *et al.* from Berlin reported on the combined use of Apogee and Perigee for women with recurrent vaginal prolapse [10]. They reported a cure rate of 93% and a 7% anterior compartment level 2 prolapse recurrence rate. The total vaginal length was 7.6 cm. They reported a 3% erosion rate, all in the anterior compartment. Importantly, they reported no *de novo* dyspareunia. In a very well-designed and executed randomized controlled trial with 1 year follow-up, Nguyen and Burchette reported on synthetic Perigee versus anterior colporrhaphy for women with anterior vaginal

prolapse [11]. The Perigee arm had a significantly higher success rate (89% vs 55%), and the dyspareunia rate was very low (16%) in both the Perigee as well as the traditional anterior colporrhaphy groups. Treatment of vaginal vault prolapse with the Apogee kit has been the subject of a multicenter trial reported by Lukban *et al.* in a series of 200 patients with a follow-up of 8.6 months [12]. They reported a cure rate of 92.2% with an operative time of 45.8 min. This group included synthetic and biologic Apogee kits; the cure rate with the synthetic Apogee kit was 93.3% and the apical sure rate with the biologic Apogee kit (with synthetic apical tape) was 97%. The rate of erosions was 7% and that of dyspareunia was 1%. We reported on our experience with biologic Apogee (with the synthetic arm at the apex) in 104 patients with a follow-up of 28.9 weeks [13]. We found an apical failure rate of 3.8% with an anterior compartment recurrence rate of 14.4%. These patients did not undergo kit anterior wall repair. The total vaginal length was 8.1 cm and *de novo* dyspareunia occurred in 9%.

Elevate anterior and posterior

This new internal fixation kit has been the subject of a recent multicenter trial. Six-month data were reported in abstract format, revealing cure rates of approximately 95% with a 1.5% incidence of buttock pain [14]. Clearly, longer-term reports are required to better analyze this novel technique.

Self-made kits

Cystocele repair via a transobturator passage with Surgipro™ mesh (Covidien, Mansfield, MA, USA) was reported by Eboue *et al.* in 113 patients with 1-year follow-up. An erosion rate of 6.5% was found with a failure rate of only 2% [15].

Complications

As with any novel, widely marketed surgical technique, controversy has resulted, especially as related to reported complications of vaginal mesh usage. The fact that anatomic outcomes are improved over traditional repair (especially in the anterior compartment) is fairly well accepted by the pelvic surgical community. However, complications have been reported and have lead to concerns regarding appropriate indications and reporting of complication rates, and to discussions regarding regulatory requirements prior to marketing of a novel implant (the US FDA 510K process for new product approval). Much of the controversy and debate has been emotionally based as there are insufficient data have to make educated statements about the actual complication rates expected with vaginal mesh usage. In fact, the developers of the TVM/Prolift kit reported that, in their opinion, complications of vaginal meshes are often overestimated, sometimes over emphasized, and often poorly described and managed [16]. In their compilation of Prolift cases (1882 interventions), complications included mesh exposition (12%), prosthetic contraction (17%), and *de novo* dyspareunia (9%). The reader will have their own opinion about whether these are high, low or expected rates.

Dyspareunia

Functional sexual disorders can have a markedly negative quality-of-life impact on a patient. Reported dyspareunia rates with synthetic kits have ranged from 0% to 18%. Perhaps most important is the *de novo* dyspareunia rate in a subject who has had normal sexual function prior to her prolapse repair. Lowman *et al.* focused on sexual function after Prolift and reported a 16.7% dyspareunia rate [17]. Other series have reported lower rates of 4–5 % (see Table 145.1) and as low as 0% in one series [10].

Mesh erosions

With non-Type 1 mesh tapes such as the intravaginal sling (IVS) (Surgipro™; Covidien), ProtoGen and ObTape, lack of incorporation of the graft was likely due to its multifilament, microporous nature. These ero-

Table 145.1 Reported outcomes for Prolift.

Study	Number of patients	Follow-up (months)	Anterior (%)	Posterior (%)	Total (%)	Success rate (%)	Erosion rate (%)	Dyspareunia rate (%)*
Fatton *et al.* [4]	110	3	20	26	54	95.3	4.7	
Milani *et al.* [5]	46	12			100	91	15	18
Feiner *et al.* [6]	100	12	100			87	10	5

Aungst *et al.* [8]	335	8	20	8	71	94.8	3.8	5.5

**De novo* dyspareunia.

sions were much more concerning and frequently associated with infection, granulation tissue formation and biofilm development. Currently used meshes (Type 1 macroporous, microfilament) are not associated with this phenomenon. Therefore, most "erosions" present along the suture line and are likely due to a defect in the healing process along this line, due to suture line separation and/or hematoma formation. Reported erosion rates range from 2% to 25% (see Table 145.1). Local therapy with antibiotics and vaginal hormones can lead to resolution in up to 44% of cases [18], and therefore local estrogen therapy should precede any surgical therapy. It has also been found that commercial kits are associated with a lower erosion rate compared to self-fashioned mesh augmented vaginal repairs (11% vs 23.6%) [19].

Overall, mesh erosions should be handled rather conservatively. There is no need to remove the entire implanted mesh as the mesh is not being rejected or infected. Removal of the exposed mesh with mobilization of the adjacent vaginal epithelium and closure of the mesh defect, followed by tension-free closure of the vaginal epithelial defect under hemostatic conditions, should result in resolution of mesh erosion/exposure in the vast majority of cases.

Mesh contraction or shrinkage

This represents one of the most significant potential consequences of mesh implantation and emphasizes the importance of tension-free implantation of synthetic mesh. An average shrinkage of 25–30% has been reported after implantation in humans. An experimental abdominal wall rat model has shown a shrinkage rate of up to 40% [16]. In a recent series, Finer and Maher reported on 17 patients with mesh contraction; all patients presented with dyspareunia and focal tenderness over the contracted portions of the mesh. Mesh erosion as well as tightness and shortening of the vaginal canal were present in a significant number of cases. After mobilization of the mesh from underlying tissue, division of fixation arms and excision of contracted mesh, 88% of patients reported a substantial reduction of vaginal pain and 64% a substantial reduction in dyspareunia [20]. It is thus clear that the postoperative occurrence of vaginal pain and/or dyspareunia must be discussed with patients during the preoperative consent process, as a small, yet significant, percentage of patients will require surgical intervention to alleviate any problematic erosion and/or pain.

De novo stress incontinence

This has primarily been studied in anterior compartment mesh kits. If a sling is *not* performed in stress-incontinent women undergoing anterior mesh kit repair, cure of the stress incontinence is reported to occur in between 69% and 87.5% of patients [21, 22]. In previously continent patients, a *de novo* stress incontinence rate of 21% has been reported [22]. Therefore, preoperative prolapse-reduction urodynamic testing should be performed in order to identify patients with potential stress incontinence. Most surgeons would recommend performing a concomitant stress incontinence procedure at the time of kit mesh repair. If a sling is not performed, the likelihood of subsequent *de novo* stress incontinence should be discussed with the patient, as well as the potential need for a subsequent sling procedure as an outpatient.

Prolapse recurrence

Overall, prolapse recurrence rates with synthetic kit use are relatively low, ranging from 5% to 20%. These recurrences typically occur as apical or apical anterior recurrences due to detachment of the synthetic mesh from the apical attachment at the sacrospinous ligament, ischial spine or other supporting structures. It must be noted that the deeper dissection required for these mesh repairs leads to a typical appearance of a recurrent prolapse. This typical appearance entails an apical enterocele with no underlying endopelvic fascia. Therefore, a subsequent vaginal mesh procedure would be quite difficult. In our experience, an apical recurrence following a synthetic mesh kit repair will require an abdominal sacrocolpopexy in order to effectively repair the prolapse. During this procedure, we will incorporate the suspending mesh to the most superior edges of the implanted mesh anteriorly and posteriorly in order to recreate support integrity to the vaginal canal. This can be quite troublesome in an elderly patient in whom the abdominal procedure may have significant associated morbidity.

Bladder perforation

Bladder perforation during performance of a kit procedure has been reported to occur in 2–3.4% [23, 24]. This complication should be readily identified on cystoscopy intraoperatively. Therefore, the need for cystoscopy after passage of the anterior trocars is imperative and should be performed prior to connection of the mesh. In advanced prolapse repairs with mesh kits, cystoscopy as well as a rectal examination should be performed routinely to identify any visceral damage.

Other complications

These include fistula formation as well as hematoma [25, 26], which are associated with any reconstructive or needle-type vaginal procedure. They do not appear to

occur in any greater percentage of cases with mesh kits compared to currently used sling procedures.

Future prospects in mesh kit utilization

There is currently much biomechanical engineering work directed at optimizing the construct of synthetic meshes implanted for the treatment of vaginal prolapse. The ideal mesh is yet to be identified. However, current advances in the construct of Type 1 mesh material with lighter, larger pore meshes are a demonstration of improvements in the science of this area of surgery. The future holds for lighter meshes with wider weave and less voluminous construct. It is likely that nonpermanent grafts will be developed, which will enhance deposition of a new and stronger endogenous collagen. The move towards internal fixation of supportive grafts is seen quite positively. It is likely that improvement in soft tissue fixation mechanisms will lead to greater longevity of meshes and less likelihood of detachment from apical supporting structures.

Currently, it appears fairly clear that mesh kits are here to stay. The growing need for durable repair of vaginal prolapse has led to increased bioengineering efforts at developing the ideal kit and suspensory materials. For now, surgeons should focus their efforts on careful selection of patients who may benefit from a prolapse kit, as well as improving their surgical skills in order to minimize complications related to kit usage. The preoperative consent process, informing patients of the risks, benefits, and possible complications of mesh usage, remains a crucial element in the care of women with advanced genital prolapse.

CHAPTER 146

Male Slings for Treatment of Post-Prostatectomy Incontinence

Ajay Nehra & E. Fred McPhail
Mayo Clinic Department of Urology, Rochester, MN, USA

Epidemiology

Prostate cancer is the most prevalent malignancy among men in the USA, and surgical options include radical prostatectomy, performed using the retropubic or robot-assisted laparoscopic approach. Oncologic outcomes are overall favorable, and much attention has been paid to quality of life among men treated surgically for prostate cancer. Post-prostatectomy urinary incontinence is bothersome to patients, and varies in prevalence depending on the center and also due to the lack of a standardized definition of incontinence [1]. However, reported continence rates at high-volume centers are as high as 91–98% and may reach 95% after 1 year [2, 3]. Rates may vary by surgical technique, but also by patient demographics. It is reported that men younger than 50 years old are overall less likely to develop post-prostatectomy incontinence than men older than 70 [4].

Pathophysiology of male continence and post-prostatectomy incontinence

In the male, two sphincteric mechanisms work in concert to provide urinary continence. The proximal sphincter, comprised of smooth muscle fibers at the bladder neck extending to the bulbar urethra [5], is under autonomic control, while the distal sphincter is comprised of both striated and smooth muscle fibers extending from the verumontanum to the bulbar urethra [6], and is innervated by both unmyelinated autonomic and myelinated somatic nerves [7]. Magnetic resonance imaging (MRI) and cadaveric dissection studies have demonstrated the length of the distal sphincter to range from 1.4 to 2.4 cm [6, 8, 9]. The smooth muscle fibers of the distal sphincter lie internal to the striated fibers and are contiguous with the smooth fibers of the proximal sphincter [5]. Myers suggests this complex, known as a rhabdosphincter, should be thought of as the "sphincteric urethra" (Figures 146.1 and 146.2) [6, 10]. In the physiologically normal male, the proximal sphincter is responsible for providing resting continence.

Urinary incontinence following surgical prostatectomy may be influenced by a variety of factors, including insufficient sphincteric activity, detrusor overactivity, or anatomic abnormalities involving the bladder or vesicourethral anastomosis [11]. In patients who undergo surgical prostatectomy, destruction of the proximal sphincteric mechanism may occur. Many of these patients retain urinary continence solely by action of the distal sphincteric complex. At rest, this is maintained by apposition of urethral tissues, and resting tone provided by smooth and striated fibers within this sphincteric complex. In response to increases of abdominal or detrusor pressure, and during voluntary inhibition of flow in these patients, voluntary activity of the rhabdosphincteric fibers may occur, in conjunction with associated contraction of levator ani fibers, in order to maintain urinary continence [11, 12]. Stress urinary incontinence (SUI) related to deficiency of the external sphincteric mechanism is the most frequent type of incontinence following radical prostatectomy. Several studies have demonstrated urodynamic evidence of intrinsic sphincter deficiency (ISD) in the majority of patients with post-prostatectomy incontinence, ranging from 83–90%

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

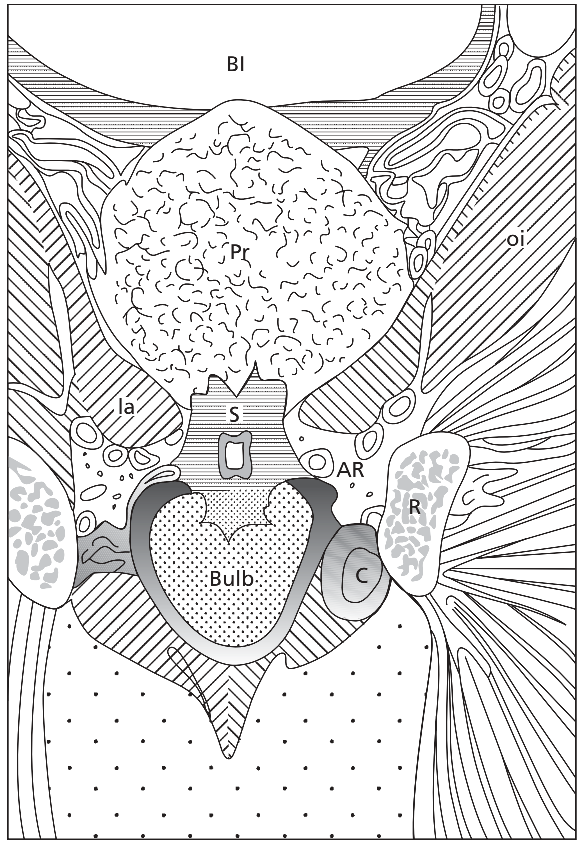

Figure 146.2 Structural anatomy of the striated urethral sphincter (s) and spatial relationship to the prostate (Pr), levator ani (la), bulbous urethra, corpus cavernosum (c), ischiopubic ramus (R), and anterior recess of ischioanal fossa (AR). Bl, bladder. (Used with permission of Mayo Foundation for Medical Education and Research.)

[13–15], this is the only urodynamic finding to account for incontinence in 60% of patients [16]. Thus, clinical and urodynamic evidence supports SUI caused by sphincter deficiency as the most common cause of post-radical prostatectomy incontinence. It is important, however, to note that transient urodynamic detrusor overactivity may be experienced in 2–77% of men following radical prostatectomy and may persist for up to 1 year [2, 17, 18]. In others with bladder neck contracture and who are incontinent following prostatectomy, an overflow pattern may be present.

Management

Continence following radical retropubic prostatectomy is recognized to increase over time. In the initial postoperative period, reassurance and psychologic support, as well as conservative therapy, including pelvic floor muscle strengthening exercises, timed voiding, and avoidance of dietary bladder irritants, may be helpful. Randomized prospective trials have reported quicker return to continence in patients who have undergone pelvic floor strengthening exercises [19, 20]; however, others have reported that this has not been true for patients with severe incontinence and does not extrapolate to long-term continence outcomes [21]. Additionally, patient factors including age, comorbidity, and preoperative voiding dysfunction, as well as neurovascular bundle preservation during prostatectomy, may influence postoperative return to incontinence.

Serial evaluation of urinary incontinence should be performed at regular follow-up visits during the first year after prostatectomy. Among patients who have persistent post-prostatectomy incontinence, many will consider surgical therapy. The artificial genitourinary sphincter (AGUS) was introduced in 1973 [22] and in its current form, the AMS 800 AUS (American Medical Systems, Minnetonka, MN, USA), has been associated with high success rates (61–96%) [23, 24] and minimal morbidity in appropriately selected patients [25]. It has long been the standard of care for surgical treatment of post-prostatectomy SUI.

Male urethral sling

The male urethral sling has recently been increasingly used for the treatment of mild-to-moderate post-prostatectomy SUI. Placement of a male urethral sling was first described in 1998 by Schaffer *et al*.; they placed

Dacron bolsters beneath the bulbar urethra and anchored these to the abdominal rectus fascia [26]. Since that time, a variety of mechanisms have been employed by which to apply passive external urethral compression with male slings. The rationale for using male urethral slings for post-prostatectomy incontinence is that, like the AGUS, their placement is minimally invasive. They are, however, less expensive than AGUS devices, and unlike the AGUS, slings provide fixed urethral resistance and/or repositioning that potentially enables better physiologic voiding [27]. Surgical treatment of male stress incontinence with urethral slings raises the question of *de novo* obstruction or associated urodynamic changes. This question was evaluated by Davies *et al*. who performed baseline and 3-month postoperative urodynamic testing on 13 patients undergoing placement of AdVance® (American Medical Systems Inc) male urethral slings for post-prostatectomy incontinence. At 3 months postoperatively, Valsalva leak point pressure (VLPP) significantly improved from 29.3 to 46.6 lb ($P = .03$), but there was no difference in baseline and postoperative detrusor voiding pressure, maximum or average flow rates, or postvoid residual (PVR) volume [28].

Bone-anchored slings

Comiter *et al*. first reported using male bone-anchored urethral slings in 2002 [29]. The commercially available InVance® system (American Medical Systems Inc) uses a disposable battery powered applicator to drive 5-mm self-tapping titanium screws into bone of pubic rami with preattached 1 Prolene suture. This anchors a pliable mesh sling composed of silicone-coated knitted multifilament polyester known as InteMesh® (American Medical Systems Inc). The mesh is porous, allowing for tissue ingrowth. The InVance system is designed for compression of the sphincteric urethra.

Several groups have reported success rates using InVance bone-anchored male urethral slings. Fassi-Fehri *et al*. reported outcomes at a mean of 6 months following InVance sling placement for post-prostatectomy incontinence. In their cohort, 50% of patients were dry (no pads), 26% improved (only 1 pad/day), and 25% had treatment failure. Overall success was 75%, and success was less likely in patients who had either severe urinary incontinence or a history of pelvic radiation. Success as defined by cure or improvement of incontinence was more likely in patients who had mild (90%) or moderate (76%) urinary incontinence. These authors speculate that periurethral fibrosis may contribute to failure in patients who have had radiation therapy [30]. Similar results with the InVance bone-anchored sling were found by Rajpurkar *et al.* who reported higher success using InVance slings in men with mild (83%) incontinence than in those with severe (50%) incontinence [31]. Immediate and intermediate continence results using InVance slings were recently reported by Guimaraes *et al*. who noted cure of incontinence in 70% of patients at 3 years and 66% at 4 years, as defined by wearing no pads [32]. Improvement as defined by requirement of less than half the pretreatment number of pads was noted in 20% by 3 years. In the short term, cure was noted in 67%, improvement in 25%, and failure in 8% of patients. Additionally, prevalence of minor complications in this interval was also reported among this group of patients and included transient elevated PVR volumes in 10%, sling explanation in 3% due to infection, and revision in 2% due to bone anchor dislodgement.

Some concern has been raised concerning bone infection in the setting of bone anchors. The risk of this has been examined in the female reconstructive literature and its prevalence is as low as 0.6% [33]. To date, no bony infections have been reported in males who have undergone placement of bone-anchored slings, possibly owing to lack of the vaginal flora encountered in female transvaginal surgery.

Long-term results with the InVance bone-anchored sling were recently reported by Carmel *et al* [34]. In that report, 45 patients with post-prostatectomy incontinence underwent InVance sling placement along with regular 2, 6, and 12 month, and yearly follow-up including pad testing, urodynamics, history, and UCLA/RAND and American Urological Association (AUA) symptom score data for a median follow-up of 36 months: 36% of patients were dry, 40% improved, and 24% reported failure. The vast majority of patients (86%) considered themselves cured or almost cured, and 72% were satisfied or very satisfied with the procedure. Complications were temporary perineal numb sensation lasting 1–3 months in 22%, temporary urinary retention in 7%, overactive bladder in 4%, *Clostridium difficile* colitis in one patient, and mesh infection resulting in removal in one patient. Similarly, a recent French multicenter study described treatment success and predictors of failure among 84 patients treated for incontinence with InVance male slings. In this study, at a mean of 20 months, 45% of patients were dry, 26% improved, and 29% had treatment failure. Univariate analysis identified three features as predictors of treatment failure: severe urinary incontinence, urodynamic instability, and a history of bimodal therapy for prostate cancer including radiation therapy. Failure rate was 67% if two or more of these factors were present versus 25% if one or none was present ($P = .013$) Bimodal therapy was the sole independent predictor of failure in multivariate analysis in this study [35]. Fischer *et al*. used a risk analysis model to predict success in 62 men treated for post-prostatectomy incontinence with bone-anchored slings and found that among several factors [time from

treatment causing incontinence, age, abdominal leak point pressure, pad weight testing, maximum bladder capacity, detrusor overactivity, International Prostate Symptom Score (IPSS), and urinary distress inventory (UDI-6)] only preoperative pad weight of less than 423 g/day was a predictor of success. Patients with less than 423 g/ day leakage had a 71% chance of success and were six times more likely to have success as defined by perception of very much or much better on Patient Global Impression of Improvement (PGI-I) questionnaires [36].

Transobturator slings

Whereas bone-anchored male slings function by fixed urethral compression, transobturator slings were subsequently developed based on the concept of proximal relocation of the sphincteric urethra. Rehder and Gozzi described a novel technique for placement of a polypropylene tape beneath the bulbar urethra using the transobturator approach in a series of four cadaveric as well as 20 human male patients [37]. The middle part of the tape was fixed distally to the bulb and proximally to the perineal body, and when tension was applied to the ends of the tape, the proximal anterior urethra was relocated proximally by a distance of 3–4 cm, effectively lengthening the membranous urethra. Baseline and postoperative video urodynamics in the clinical series confirmed that at rest, the bladder neck and posterior urethra were more occluded, and the bladder neck was closed and more elevated than at baseline. Additionally, postoperative video urodynamics demonstrated a more elongated membranous urethra during micturition, having increased from a mean of 3 mm to a mean of 17 mm following placement of the tape. Urethral pressure profilometry in the same series demonstrated an improvement of supine mean urethral closing pressure at rest from 13.2 cmH_2O preoperatively to 86.4 cmH_2O postoperatively.

The rationale for treating post-prostatectomy male incontinence by transobturator tape is based on the theory that post-prostatectomy men with partially intact external sphincteric complexes may develop incontinence due to urethral hypermobility, resulting in urethral or perineal descent from the pelvis, possibly associated with coexistent levator laxity; hence proximal relocation of the sphincteric urethra may result in improved continence [37, 38].

Gozzi *et al*. reported continence results among 67 post-prostatectomy patients treated with transobturator urethral slings [39]. At 3 months postoperatively, 52% were cured (no pads) and 38% had improvement of incontinence (1-2 pads/day). Complications included persistent incontinence requiring sling replacement in five patients (7%), suprapubic drainage for postoperative retention in 11 patients (16%), and subsequent placement of AGUS in two patients (3%). A recent prospective multicenter trial by Cornel *et al*. examined pad weight test results at 3 months and 1 year following AdVance (American Medical Systems Inc) transobturator sling suspension in 37 men with post-radical retropubic prostatectomy (RRP) and post-transurethral radical prostatectomy (TURP) incontinence [40]. The overall cure rate was 14.3% at 3 months and 9% at 1 year. Improvement was noted in 42.8% at 3 months and 36.5% at 1 year. Pad testing demonstrated worsening incontinence in 14.2% of patients postoperatively. Additionally, urinary bother recorded by VAS was improved at 3 months postoperatively, but was not significantly different at 1 year. VAS score correlated with objective cure or improvement on pad weight testing. Interestingly, cure as defined by pad weight testing occurred only in the RRP group, with no patients cured who had TURP or radiotherapy in addition to RRP. Preoperative incontinence using pad weight cut-offs of 200 and 400 mL/day, or fewer or greater than 5 pads/ day, was not significantly associated with pad testing or VAS improvement. The results in the report by Cornel *et al.* [40] are less favorable than in those in Gozzi *et al.*'s series [39]. The reason for the discrepancy between the series is unclear, but Cornel *et al.*'s study does suggest that patients who have had TURP or radiotherapy may not benefit from transobturator sling placement based on the definitions used for successful outcome in their study. Additionally, it is important to note that when compared to continence results with AGUS, outcomes reports with male slings have been widely variable and difficult to interpret owing to small, single-center studies with short follow-up periods and variable definitions of success.

Patient selection and evaluation

Careful evaluation and patient selection is important when considering treatment of male urinary incontinence with a male sling. Candidates should be at least 1 year post prostatectomy and have mild-to-moderate SUI. Features that might be predictive of failure should be considered, including high-volume incontinence, comorbidity, and urgency component to the incontinence. Caution should be exercised when considering treatment of patients who have undergone radiation therapy. All patients should have a careful history taken. Physical examination should be performed for documentation and gross quantification of stress incontinence. Cystoscopy should be performed on all candidates to confirm presence of some sphincteric coaptation, as well as absence of stricture or bladder neck contracture. When history suggests mixed incontinence with urgency, or if neurologic disease exists, urodynamics evaluation

should be performed to evaluate detrusor activity. As with all interventions for incontinence, caution should be used when patients have detrusor overactivity.

Detrusor hypocontractility is a contraindication for sling placement, whereas for such a patient an AGUS may still be appropriate. Recurrent nephrolithiasis, urothelial carcinoma, unstable stricture disease, or other conditions requiring frequent transurethral access are contraindications to sling placement. Additionally, patients who have previously undergone incontinence surgery with either a sling or AGUS may be more likely to benefit from AGUS than a sling [41]. Patients with risk factors for sling failure, including severe stress incontinence or history of radiation therapy may be better served by AGUS than a male sling. Despite these risk factors, however, male slings may be indicated in otherwise appropriately selected patients with insufficient hand function to operate an AGUS.

In the absence of risk factors for sling failure, many patients may benefit from either a sling or AGUS and should understand the merits of each in the process of making an informed decision.

Surgical technique

Placement of bone-anchored slings will be described, but emphasis is given to the placement of the more commonly used transobturator male slings.

InVance bone-anchored slings

The appropriately chosen patient is positioned under general anesthesia in the high dorsal lithotomy position with the perineum prepped and draped. A 14F urethral catheter is placed for bladder drainage and urethral identification. A 4-cm midline perineal incision is made over the urethra after palpating the catheter and ischial tuberosities. Dissection is carried down over the urethra, leaving the bulbospongiosus muscle intact. Dissection is directed laterally until the pubic tubercle and descending pubic rami are identified. The inferior aspects of the pubic rami are identified. A Scott/Wilson or similar retractor is placed into the incision for exposure. The applicator is used to insert six 5-mm titanium screws as bone anchors into the pubic rami. Three bone anchors are placed 1 cm apart into each descending ramus, just inferior to the pubic symphysis. The most inferior bone anchor should be placed no more inferiorly on the descending ramus than at the level of the bulbar urethra. Each bone anchor is pre-attached to a 1 Prolene suture. An audible change in pitch indicates that the anchor has been inserted to the appropriate depth. The sling is a 4×7 cm sheet of pliable mesh composed of silicone-coated multifilament polyester known as InteMesh. The mesh may be trimmed to fit the patient in some cases. One side of the mesh is first tied down snugly with the Prolene sutures attached to the bone anchors in one pubic ramus. Sutures should be placed at least 1-cm medially from the edge of the mesh to provide optimal strength. The second side of the mesh is similarly tied down tightly using the Prolene sutures attached to bone anchors on the second pubic ramus. The mesh should be tied down as tightly as possible to provide maximum tension. An alternative involves intraoperative leak point determination to determine the appropriate mesh tension prior to tying down the second side of the mesh. The perineal incision is closed in three layers using two layers of 3-0 Vicryl and skin with 4-0 chromic suture to complete the procedure.

AdVance transobturator slings

The patient is positioned in high dorsal lithotomy position under general anesthesia. A 14F urethral catheter is placed for bladder drainage and urethral identification. A midline perineal incision is made (Figure 146.3) and carried down to the bulbar urethra, which is identified by palpation of the catheter. The bulbospongiosus muscle is left intact (Figure 146.4). A self-retaining Scott/Wilson retractor is placed into the incision for exposure. Two separate stab incisions are made bilaterally 1 cm inferior to the adductor longus tendon, at the approximate level of the base of the penis. An introducing trocar is passed through one of the stab incisions. The obturator ring is encountered with the trocar, which is then

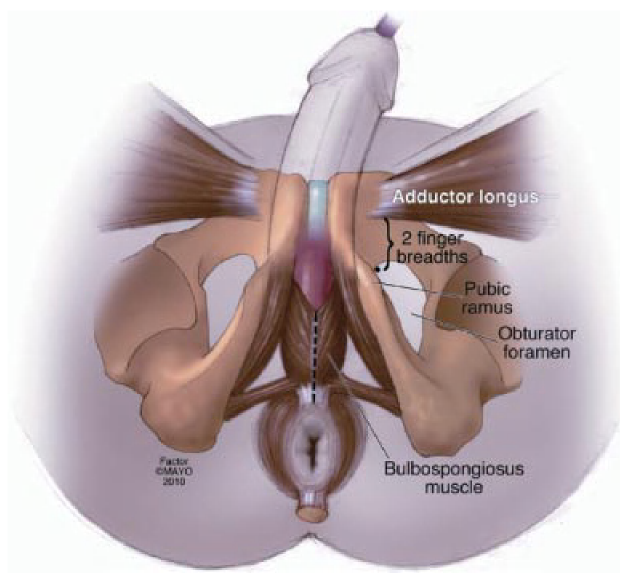

Figure 146.3 Relevant pelvic anatomy for placement of a transobturator male sling. A midline perineal incision is made. Bilateral stab incisions are made two finger breadths posterior to the adductor longus tendon at the level of the base of the penis.

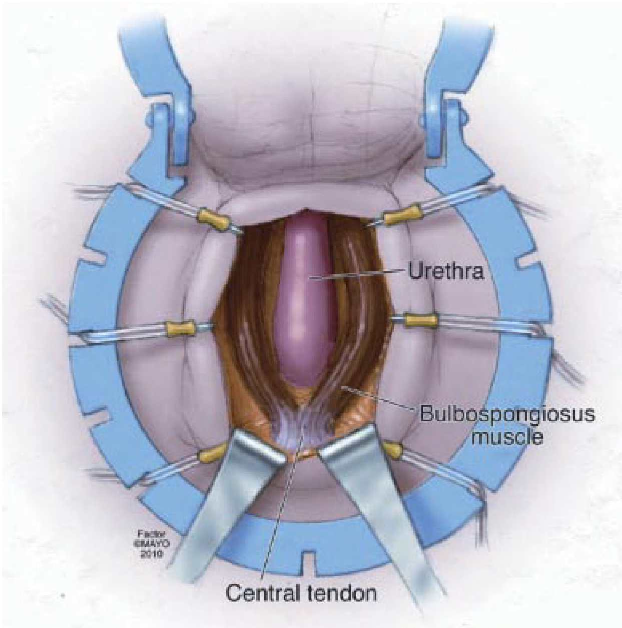

Figure 146.4 Urethra is identified within the midline perineal incision. The bulbospongiosus muscle is spared. A self-retaining retractor is placed into the incision for exposure.

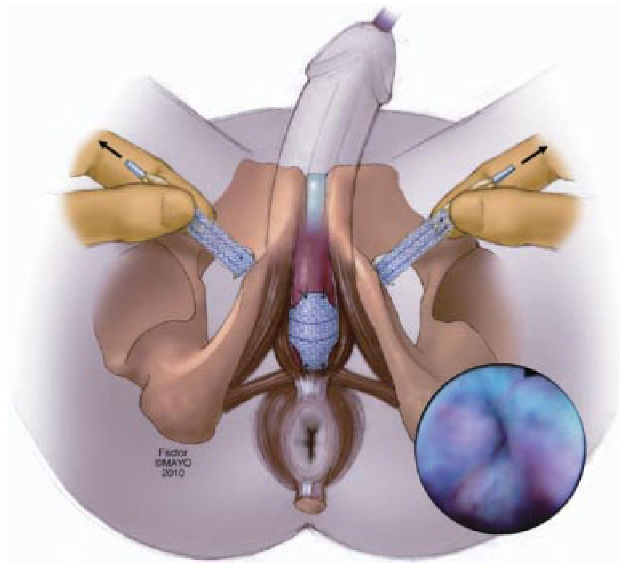

Figure 146.6 Mesh is placed flatly against the urethra and anchored in four corners with 3-0 Vicryl suture. Urethroscopy is performed, and tension is applied to the ends of the mesh under urethroscopic vision to confirm appropriate coaptation of the sphincteric urethra.

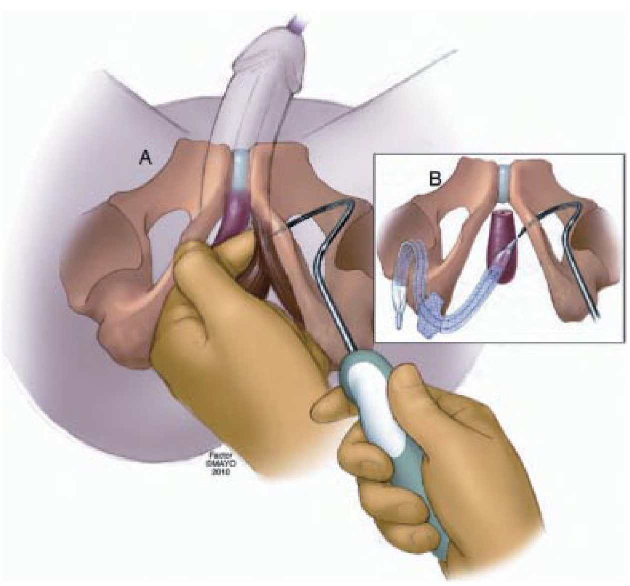

Figure 146.5 (A) A curved trocar is placed through the stab incision. The descending pubic ramus is encountered and the trocar then angled laterally and passed through the obturator ring with index finger guidance. The trocar follows the index finger into the perineal incision. This process is then repeated on the contralateral side. (B) Each end of the AdVance sling is then attached to a trocar eye and brought out through the stab incision.

advanced medially and passed through the obturator membrane and ring. An index finger is used through the perineal incision to guide the trocar out through the perineal incision. A second trocar is then passed through the contralateral stab incision in the same manner. The distal ends of the sling are passed through the eye of each trocar and brought out with each trocar through the stab incisions (Figure 146.5). The mesh at the center of the sling is placed flatly against the sphincteric urethra. Cystoscopy is performed to exclude urethral or bladder injury. Tension on the sling is adjusted under direct vision using urethroscopy so that a bulge is noted at the sphincteric urethra without obstruction of the lumen (Figure 146.6). The mesh is then fixed to the bulbospongiosus muscle overlying the bulbar urethra using one 3-0 Vicryl suture at each corner. Sleeves are removed from the ends of the mesh, and using a right angle, the distal ends of the sling and attached suture are tunneled out of separate stab incisions approximately 2 cm inferomedial to the initial stab incisions bilaterally. Sleeves are removed from the arms of the sling, and the excess mesh is excised (Figure 146.7). Stab incisions are closed with simple 4-0 Vicryl suture. The perineal incision is then closed using two layers of 3-0 Vicryl and skin using 4-0 chromic suture (Figure 146.8). Oral antibiotics are prescribed for 1 week, and strict activity restrictions are

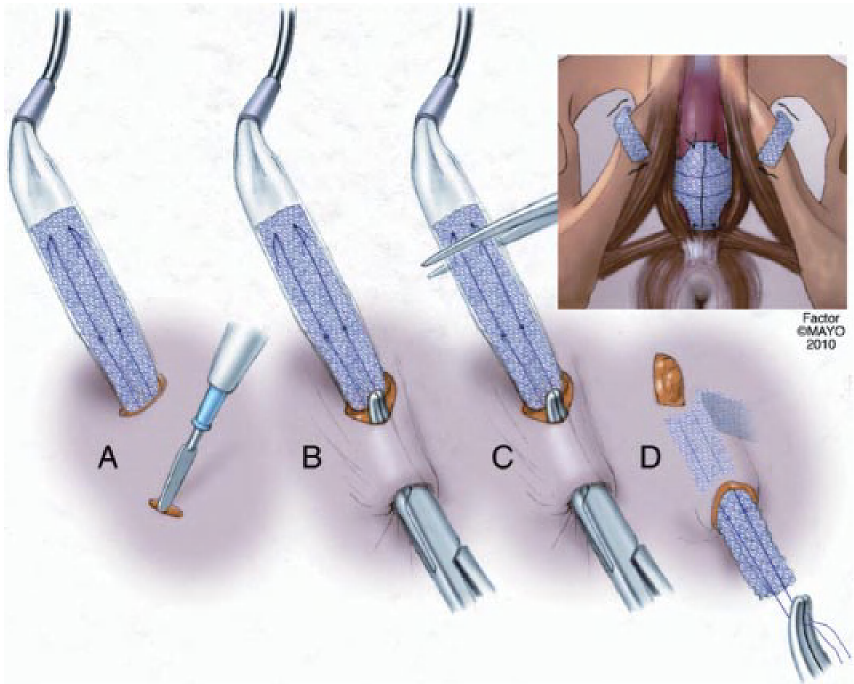

Figure 146.7 (A, B) A superficial stab incision is made 2 cm inferomedial to the stab incision bilaterally. (C) Sleeves are removed from each side of the mesh. (D) A right angle is used to create a tunnel and bring the mesh ends out through the inferomedial stab incisions. Excess mesh is trimmed at skin level.

implemented, including no hard chairs, biking, sexual activity, or lifting more than 10 lb for 2–3 months.

Coloplast Virtue male sling

The Coloplast Virtue® sling involves mesh that is fixed to two prepubic arms as well as two transobturator arms in order to provide quadratic fixation of the sphincteric urethra (Figure 146.9). This system is designed to employ principles of both urethral elevation and compression in order to improve post-prostatectomy continence.

Conclusions

Advances in the diagnosis, management, and treatment of men with SUI have resulted in various surgical options. A meticulous preoperative evaluation and long-term analysis of outcomes and results will provide insights into success following sling surgery.
